N = 42 (51%)
N = 26 (50%)

* Incidence was calculated by taking the percentage of new cases of dementia from among surviving subjects not diagnosed as demented at the previous time of assessment. (At Time 2 there was incomplete information for diagnosis in 14 cases, at Time 3 in 8 cases and at Time 4 in one case.)

Figure 2 Prevalence of dementia and incidence of demention and mortality over a six-year period in a population-based sample of 84–90 year olds ("Early cognitive markers of the incidence of dementia and mortality: A longitudinal population-based study of the oldest old" by B. Johansson and S. H. Zarit, 1997. *Journal of Geriatric Psychiatry, 12,* pp. 53–59. Copyright 1997 by John Wiley & Sons Ltd. Adapted with permission).

of Lazarus and Folkman (1984), who described coping as "constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are appraised as taxing or exceeding the resources of the person" (p. 14). Because appraisal is a crucial component, self-attributions and personal control come into focus. Personal control, locus of control, self-efficacy, and other similar concepts all refer to the individual's feeling of being in control or lacking control over life in general or in managing certain aspects, for example intellectual tasks (see, Baltes & Baltes, 1986). In this respect, coping and dimensions of personal control are also important for daily life adjustment and performance on certain cognitive tasks.

Of particular relevance for memory and cognition in this context is metamemory and metacognition, referring to people's awareness of their own strengths and weaknesses in performing memory and other cognitive tasks. For example, less effort than necessary may be invested in performance when belief exists that one's memory and cognitive capacity is too low for a certain task, and self-attributions given to actual success or failures in performance tend to reinforce these attributions. Hayslip and Panek (1993) describe the interrelations between performance experiences, self-statements, and emotional reactions in terms of a vicious cycle (see Figure 3).

Further, the relation between conceptions or self-attributions of, for example, intelligence, may be under multifactorial influence. Much of the work on conceptions of intelligence indicates that the dimensions that make up the prototypic intelligent person may vary at different periods of development and for individuals of different ages or experiental background (e.g., Siegler & Richards, 1982; Yussen & Kane, 1983). Berg and Sternberg (1992) examined whether young, middle-aged, and older adults viewed the concept of intelligence differently depending on their own age. They found that adults perceive differences in what constitutes exceptional intelligence during young, middle, and late adulthood, but also that adults' conceptions of intelligence are characterized by multidirectionality and modifiability.

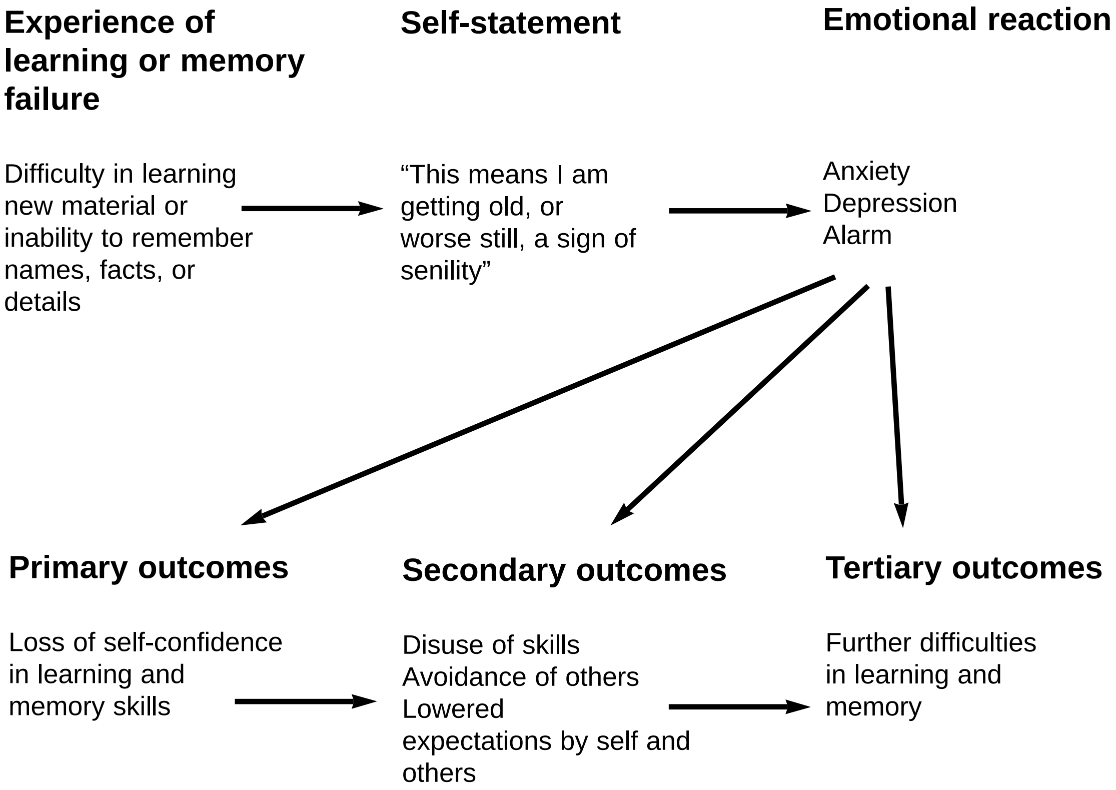
In a study of actual and perceived change in intellectual performance, Schaie, Willis, & O'Hanlon (1994) identified three groups: realists (individuals who accurately estimated actual change), optimists (those who overestimated actual change), and pessimists (those who underestimated change). This classification was based on self-reports and actual performance on several tests. Older individuals were more realistic than younger subjects on a test of number ability, while more pessimistic about verbal meaning and reasoning tests. Section 7.02.2.2.2 examines further relations between psychological well-being, self-attributions, and cognitive performance.

7.02.2.2.2 Psychological well-being

Research into the psychological well-being of elderly persons tends to emphasize prior life satisfaction and mood as important predictors. Self-attributions, in terms of subjective memory and cognition, are also concurrent markers for adjustment and well-being. Beyond normal emotional fluctuations, the interrelationships between self-reports and performance become obvious in clinical depression. An inability in the depressed person to mobilize motivation will ultimately lead to deficient performance. Depression is a prevalent and disabling mental disorder in the elderly and the symptoms tend to be more indistinguishable and often involve impairments in memory and cognition (e.g., Bäckman & Forsell, 1994), in some cases with a severity that corresponds to depressive pseudodementia (see Katona, 1994). Severity of depression seems to be correlated with the magnitude of performance deficits in tests of memory and cognition (e.g., Cipioli, Neri, Andermarcher, Pinelli, & Lalla, 1990).

Numerous studies have reported strong associations between depression and self-reports of cognitive functioning. It was, however, early recognized that complaints must be differentiated from actual performance (Kahn, Zarit, Hilbert, & Niederehe, 1979). A diagnostic scheme for different configurations of performance, complaints, and affective status was presented by Gallagher, Thompson and Levy (1980). In a meta-analysis, Burt, Zembar, and Niederehe (1995) even suggested that complaints may have a stronger association with general psychopathology than with depressive symptoms. Further studies are needed to resolve the complex interrelationships between cognitive performance, mood, and self-attributions (see Kaszniak & Ditraglia Christenson, 1995).

Zarit (1979) suggested that memory complaints also reflect "a memory and aging stereotype" that ascribes poor memory to the elderly due to their age. Such a stereotype is likely to be internalized by the elderly. Studies on self-reports show, however, a great variation, typically in the range of 40–80%, in the extent to which older people feel that their memory performance is compromised. These discrepancies may reflect sampling differences and sociocultural values. In a population-based



Experience of learning or memory failure
Difficulty in learning new material or inability to remember names, facts, or details
Self-statement
"This means I am getting old, or worse still, a sign of senility"
Emotional reaction
Anxiety
Depression
Alarm
Primary outcomes
Loss of self-confidence in learning and memory skills
Secondary outcomes
Disuse of skills
Avoidance of others
Lowered expectations by self and others
Tertiary outcomes
Further difficulties in learning and memory

Figure 3 A vicious cycle in which memory failures, self-statements, and emotional reactions tend to compromise future performance (*Adult Development and aging* (p. 158), by B. Hayslip Jr. and P. E. Panek, 1993, New York: HarperCollins. Copyright 1993 by HarperCollins College Publishers. Adapted with permission).

sample of very old Swedish people, participants were examined four times over a six-year period, and were asked to rate their own memory and cognitive ability (Johansson, Allen-Burge, & Zarit, in press). Participants typically evaluated their abilities in a positive manner (see Table 1). A subsample of 31% were, however, excluded because of dementia, which has to be taken into account when examining the figures.

These self-evaluations were scaled and further examined in relation to concurrent, prospective, and retrospective performance on a battery of memory and cognitive tasks (Johansson et al., 1997). Individuals who evaluated their memory more positively showed significantly better concurrent test performances. In addition, they also reported less depression. The study interestingly revealed that self-evaluations predicted subsequent decline in test performance, as well as onset of dementia within the next two to four years. In the retrospective analysis, more negative self-evaluations were found in individuals who two years later reported that they had experienced declining memory. The actual strength in the associations between test scores and self-evaluations were, however, quite weak. This suggests that self-evaluations are influenced by factors not covered by performance on tests. The few existing studies on the relationships between self-rated intellectual abilities and performance on intelligence and practical problem-solving tasks also show weak associations (e.g., Cornelius, 1990).

7.02.2.2.3 Summary

Present functioning should always be related to the individual's prior level of functioning. This will obviously present difficulties as we seldom have baseline information or any other detailed information about the individual's past function at the level of various abilities in focus in an assessment. It is also necessary to consider influences from demographics and to take into account the individual's own perception of memory and cognitive functioning, as well as other expressions of psychological well-being that may exert an impact on the effort invested in a certain performance. Although self-reports are closely related to psychological well-being, self-evaluations may also be formed by experiences of success and failure in performing cognitive tasks in daily life.

Table 1 Self-evaluations of memory in a population-based sample of 84–90 year olds in Sweden.

Self-evaluation	*On the whole, how would you rate your memory? (%)*	*On the whole, how would you rate your thinking and problem solving? (%)*
Good	44%	53%
Rather good	34%	33%
Neither good nor bad	8%	7%
Rather bad	5%	6%
Bad	9%	1%
	Do you experience memory failures in everyday life that makes life more difficult? (%)	*Do you experience problems in remembering what to do and say at a later occasion (prospective memory)? (%)*
No problems	82%	66%
Minor problems	17%	32%
Major problems	1%	2%
	Have you experienced any changes with your memory in the last two years? (%)	
Better now	1%	
No change	50%	
Somewhat worse now	44%	
Worse now	5%

7.02.2.3 Sociocultural Context

Aging is certainly not a context-free process (see Blanchard-Fields & Abeles, 1996). On the contrary, health status and level of functioning in later life are dependent on cumulative outcomes from numerous sources, including influences from the sociocultural context (e.g., dietary habits, transportation, and physical mobility, or the coverage and inputs by health care institutions like dentistry or preventive pediatrics). A list of potential factors would be very extensive. The differential exposure to environmental influences generally makes people different, and it is often claimed that interindividual differences increase with age (e.g., Krauss, 1980; Nelson & Daneffer, 1992). This is still an unresolved issue, but in assessing elderly persons, attending to sociocultural influences seems as important as attending to ethnicity or social class.

7.02.2.3.1 Cohort and period effects

Cohort is a concept often used in the aging literature. Cohort generally refers to people born during a certain time and therefore exposed to similar experiences that tend to make them more alike than generations of people born earlier or later (see Rosow, 1978). Thus, age differences should be interpreted taking cohort effects into account. This was noticed early when age differences found in cross-sectional studies could be ascribed to significant cohort effects. The classical example is a study by Birren and Morrison (1961), who found higher correlations between certain tests of intelligence and years of formal schooling, than with age. The important role of education has since been identified in many studies (e.g., Inouye, Albert, Mohs, Sun, & Berkman, 1993). The educational system also represents an important social institution where different methods and content, hopefully, have long-lasting but differential effects on various cohorts. Thus, the potential impact of educational differences must be considered in evaluating cognitive performance, particularly in the presence of broad age ranges.

The importance of cohort is easily observed in the educational system. In elderly Swedish cohorts most individuals have six years of basic formal schooling only, compared to more than 12 years for persons in their twenties. Even at the level of brief cognitive screening, employing devices like the MMSE, it has been suggested that different cut-offs have to be used for elderly people at different educational levels (e.g., Crum, Anthony, Basset, & Folstein, 1993). Employing more sophisticated tests, cohort-adjusted norms have to be appropriate for accurate interpretations. Other cohort influences may be identified in the political scene, for example the 1968 movement in Europe, corresponding to the Vietnam generation in the USA, or personal experiences of the world wars that affected people differently across ages.

Period effects refer, in the context of aging, to influences that affect people throughout ages. An example is the introduction of television. Some claimed that socially and intellectually rewarding activities, such as crosswords and jigsaw puzzles, hobbies and so forth were replaced by television. The Swedish expression *dumburken* ("couch potatoes") captures these assumed negative aspects of passive television watching. At the same time no one can deny the wealth of information and general world knowledge that is easily brought to the public through television. Although period effects tend to be pervasive across ages, certain influences may affect older persons differently from younger (see Elder, 1979).

7.02.2.3.2 Sociocognitive development

Memory and other cognitive abilities develop in a sociocultural context where environmental influences tend to be normatively age-graded, that is, highly correlated with chronological age. A life-span model of intellectual development based on significant inputs from the sociocultural context was formulated by Schaie (1977–78). The model distinguishes four major developmental stages. Acquisition is the major theme in childhood and adolescence, preparing the individual with basic skills and information for later life. This basic expertise includes what society defines as essential for successful socialization and crucial for the reproduction of society. In the next stage, the young adulthood period—or the achieving stage—acquired knowledge has to be applied, whether at work, in the family, or in other social contexts. The middle age period that follows is described basically as a stage where cognitive abilities involve more social responsibilities or executive roles. The reintegrative stage in old age is a period where one's interests, attitudes, and values become the important inputs for the individual. Personal meaningfulness is ascribed a major theme in this stage. The transitions between stages proceeds from "What should I know?" through "How should I use what I know?" to "Why should I know?" In aging, the individual requires more meaning in order to be motivated to engage in a certain task.

Disuse has been identified as a main source for decline in abilities that require continuous use in order to be preserved (see Kohn & Schooler, 1983; Lee, 1991). In addition to the general slowing in primary aging, disuse is generally thought of as an important input for decline in functions not practiced. Support for this hypothesis is offered by an increased performance–capacity gap with increasing age, and interventions demonstrating considerable plasticity or modifiability in primary aging (e.g., Baltes & Kliegl, 1992). Perlmutter (1986) describes a life-span view of memory in which the individual's memory capabilities reflect past experience, and where decline in capacity can be compensated for by growth in memory contents. This leads to an increasing environmental fitness and to an increasingly adapted memory system.

7.02.2.3.3 Summary

In a sociocognitive development context, aging can be understood as a change of the behavior repertoire in accordance with the individual's own preferences, besides the influences of cohort and generation. Cohort effects refer to age differences due to influences that variously have affected different birth cohorts. Period effects, on the other hand, emphasize the need to consider certain sociocultural influences as more pervasive across ages. The actual impact of these influences may, however, vary depending on the age of the individual. The specific organization of society also imposes certain age-graded roles and tasks. Although a fixed stage model like Schaie's (1977–78) tends to neglect interindividual differences, it directs attention to the fact that certain tasks may be perceived quite differently depending on the differential use of intellect at different ages. This view emphasizes a need to consider what types of cognitive tasks could be employed in examining elderly people in an age-fair manner. The latter includes an ecological aspect of memory and cognition.

7.02.2.4 Cognitive Demands and Everyday Functioning

In cognitive aging research, age-related decline in a variety of abilities such as visuospatial functioning or episodic memory performance is well documented. In other types of task one may find that performance remains relatively stable or even improves across the adult life span. Preserved abilities are likely in tasks tapping general knowledge or language-related skills. Our knowledge is sparse on how this translates into everyday functioning (e.g., Salthouse, 1990; Searight & Goldberg, 1991). In clinical practice, the geropsychologist may have to resolve whether it is likely that impaired performance on, for example, tests of visuospatial ability is related to difficulties in everyday functioning. In other words, to what extent is it possible to infer, from certain test results, that an individual is incapable of performing adequately in everyday life? A patient with extensive prefrontal damage may be significantly impaired in everyday life, yet perform within the normal range on neuropsychological tests (e.g., Stuss & Benson, 1986). Another patient may score below cut-off for normal performance, but demonstrate adequate performance on a variety of everyday tasks, perhaps because these tasks are overlearned and because adequate performance is defined according to lower demands because of old age.

Clearly, everyday performance has to be related to the demands of daily living and available support systems, as well as baseline capacity. One can discern two major explanations for the understanding of discrepancies between elderly people's daily-life performance and scores on test of memory and cognition. The first is based on the idea that standard tests are inadequate because they simply do not measure the relevant processes underlying daily-life functioning. Thus, the assumption is that tests and everyday life differ in terms of the mechanisms involved. The other, functional, explanation, relates to age fairness emphasizing unfamiliarity and task novelty as significant inputs for lower test performance in the elderly (e.g., Bruce, 1991).

7.02.2.4.1 Cognitive mechanisms and tasks

The experimental and clinical test traditions have been criticized for their predilection for using artificial materials for remembering, or as stimuli in problem solving. The claim is that these methods have restricted relevance for the understanding of memory and cognition in everyday life (see Willis, 1996). In this vein, Neisser (1978) even suggested that naturalistic studies of memory would be more productive than their laboratory counterparts.

Some authors have argued that standard experimental tasks, in which elderly people demonstrate worse performance than younger ones, are not valid as indicators of everyday performance for older adults (e.g., Baltes & Willis, 1979; Berg & Sternberg, 1985; Labouvie-Vief, 1982, 1985). However, in spite of many efforts to develop more naturalistic measures, such as memory for texts or television programs, the results do not confirm the expected elimination of age effects or even attenuation of age differences (e.g., Denney, 1989; Hartley, 1989; Salthouse, 1983). On the contrary, performance on standard memory tasks and on more ecologically relevant tasks seem to provide similar results. It has also been claimed that certain tests may have a potential disadvantageous impact because different age groups are not equally experienced with stimulus materials or experimental and clinical tests of cognitive functions. There is, however, rather convincing evidence that differences in experience or unfamiliarity with stimulus materials cannot solely account for observed age differences (e.g., Salthouse, 1987, 1990).

The claim that standard tasks do not accurately portray everyday performance led some researchers to construct tests better suited for elderly persons, so called age-fair tasks. An example is the brief battery of tests based on ideas of ecological relevance and used by Johansson, Zarit, and Berg (1992) in studies of the oldest old. The tests, Coin Test, Clock Test, and MIR ("Memory in Reality"), were deliberately designed to minimize floor effects and to differentiate performance in cognitively impaired individuals. Age-fair testing is highly interrelated with *ecological relevance*, referring to naturalistic studies of memory and cognition. Both concepts emphasize the functional aspects, not that different mechanisms are involved in everyday performance compared to an experimental or clinical context. Ecological relevance refers to the congruence between task demands and demands imposed in everyday life. In other words, to what extent do the obtained pattern of results using psychometric or laboratory tasks generalize to situations in the everyday life of the individual? In a study by Cockburn and Smith (1991), subjects were tested with various measures of fluid and crystallized intelligence (see Section 7.02.3.2.1) in order to examine the predictive value of these tests for performances on a range of everyday memory problems, including analogs of situations met in daily life, such as remembering names or asking for the return of a hidden possession. Crystallized intelligence showed low predictive power, while fluid intelligence was a better predictor, although the authors concluded that cognitive decline in aging involves more than a simple decline in fluid intelligence. In another study on everyday memory, West, Crook, and Barron (1992) found that a measure of crystallized intelligence, vocabulary, played a significant role for almost every memory measure examined.

7.02.2.4.2 Tests of functional abilities

In some cases it may be preferable to perform a functional assessment of the client's abilities in parallel with cognitive testing. For this, clinicians have at their disposal several standardized methods measuring activities of daily living (ADL; e.g., Kane & Kane, 1981). These instruments assess functions that are associated with basic self-maintenance such as dressing, feeding, or hygiene. Furthermore, there are other instruments assessing a broader domain of more complex abilities such as managing transportation, communication, self-medication, or financial transactions. This domain of abilities is often called instrumental activities of daily living (IADL; e.g., Kuriansky & Gurland, 1976). One example is the Community Competence Scale (see Grisso, 1986). Using a multidimensional battery, Zarit, Johansson, and Berg (1993) found strong associations between cognitive impairment, ADL, and IADL in the oldest old. Results like this demonstrate that cognitive abilities are necessary prerequisites for adequate performance, although the sensitivity may be low within normal ranges of functioning.

7.02.2.4.3 Summary

Our understanding of memory and cognition are greatly determined by procedures and methods used in research. There seems to be no reason to believe that experimental and psychological tests measure functions other than those also constituting the basis for everyday functioning. The relation between test performance and level of functioning in daily life appears, however, to be influenced by numerous other factors such as social demands, support-systems, or the individual's level of experience. Everyday functioning of the client is of importance. In assessing elderly people, the degree to which test demands overlap with demands of daily life ought to be taken into consideration. Much effort has been invested in constructing tasks more suitable for the oldest people. Research suggests that results on various psychometric tests may show weak associations with everyday functioning. The inclusion of an assessment of actual performance in everyday life, such as IADL measures, can provide additional information of value to the geropsychologist.

7.02.3 MEMORY AND OTHER COGNITIVE ABILITIES

This section reviews some select research on memory and cognition in relation to current theory. Some brief outlines of models of memory, as well as processes and components involved in other cognitive abilities, will be provided. The reader is reminded of the analytical scheme (Figure 1) presented in the introductory section when critically examining reported findings and the bases for interpretations. In doing so, it is important to keep in mind the multifactorial influences on cognitive performance in old age. Furthermore, apart from noncognitive influences, it is also important to recognize that most published studies are cross-sectional and consequently demonstrate age differences only, and that the bulk of research includes convenience samples recruited for studying cognitive mechanisms or potential age-related differences in various abilities. Most studies provide no detailed information concerning physical health (relating to the distinction between primary and secondary aging). To what degree the failure to do so has influenced the typical picture of cognitive aging remains yet to be elucidated. Last, few studies of memory and cognition have included individuals beyond 80 years, which limits our understanding of the very old and oldest old.

7.02.3.1 Learning and Memory

Learning and memory represent highly interrelated processes, and the study of either requires understanding of the other. Studies of learning tend to emphasize the acquisition of new behaviors and information, while memory refers to processes involved in the retention and retrieval of what has been acquired. Learning and memory are here treated separately from other aspects of cognition because of the wealth of information available and the extensive research in the area. This subsection provides first a framework, out of several possible, for the understanding of learning and memory. In addition, there is an examination of the significance of task properties, here defined as levels of cognitive support, for variations in episodic memory performance. Finally, some relevant research is reviewed with focus on the oldest. The review is largely restricted to episodic memory, because this memory system has proved to be most affected by age, in addition to its sensitivity to depression, dementia, and other illnesses that are prevalent in aging.

7.02.3.1.1 Types of learning

Learning may mean many quite different things. It may refer to the mastering of a new skill such as learning how to ride a bicycle. The resulting procedural or motor-based memories are formed without awareness. This general area of learning and memory has been reviewed by Chiarello and Hoyer (1988) and Graf (1990). Learning may also mean acquiring and changing habits. Behavior modification is an example of this type of learning in clinical practice. Learning may further mean the acquisition of new information. This is something we all do in school. We may still remember what date World War One started, but not when that information was acquired. This is generally what we refer to as semantic memory.

This subsection restricts itself to episodic memory, and learning is concerned with the remembering of personal incidents that are, in most cases, not very distant in time. Tested persons are presupposed to remember where they picked up the requested information. The typical example is a test of memory where the psychologist reads a list of words or sentences, and the client is later asked to recall as many of the words or sentences as possible of those that were presented some minutes ago.

7.02.3.1.2 Models of memory

Many researchers classify memory phenomena in terms of memory systems, although the results are often analyzed in terms of various processes operating within these systems. For the clinician, the system model is perhaps the most intuitive, since it alludes to specific tasks. Before proceeding to some of the systems identified in modern experimental psychology, we choose as the point of departure a model that has exerted an enormous impact in the development of later theoretical accounts. This is the "Multistore" model of memory proposed by Atkinson and Shiffrin (1968). In clinical practice, their line of reasoning is perhaps still sufficient. Basically, this model of memory distinguishes between the sensory store where new information enters through sensory stimulation, the short-term store where the information is subjected to conscious mental activity, and the long-term store which is thought of as a more or less permanent store of information.

As a general guideline, it may be sufficient to distinguish between recent and remote memories, or between short- and long-term memory. These subdivisions are, however, somewhat complicated in terms of test materials. We therefore now turn to selected parts of the system model which are somewhat more clear for clinical purposes. For more detailed discussions, consult Baddeley (1990) or Parkin (1993).

Short-term memory is analogous to primary memory in that it represents the locus of conscious mental activity. Early accounts of primary memory (e.g., Waugh & Norman, 1965) stated that this system registers and retains incoming information in a highly accessible form for a short period of time after input. This conception of primary memory has been elaborated in recent years (e.g., Baddeley, 1986). It may be useful to distinguish primary memory (holding information in consciousness) from working memory (simultaneously holding information in mind and elaborating on or using that information in combination with other incoming information). Roughly, in terms of tests, this corresponds to the difference between Digit span forward and backwards (Wechsler, 1981).

The long-term store may, in terms of memory systems, be further subdivided into episodic and semantic memory. Episodic memory refers to memory of personally experienced events with a reference both in time and space, that is, we remember something we have experienced, and that memory is associated with information about when and where the information was encoded. The command "recall as many of the words as possible from the list I presented to you 10 minutes ago" evokes episodic memory. Semantic memory is memory for general knowledge (Tulving, 1983, 1985). The information task of the Wechsler Adult Intelligence Scale (WAIS) battery corresponds to a test of semantic memory.

7.02.3.1.3 Episodic memory

Most researchers agree that age differences in performance are most likely to occur in episodic memory tasks, that is, in tasks requiring conscious retrieval of information acquired in a particular place at a particular time (see Kausler, 1994; Light, 1991; Salthouse, 1991, for reviews). However, memory performance in very old age has received relatively little empirical attention. The available evidence is mixed as to whether there are differences in episodic memory functioning among different cohorts of old and very old adults. Most studies of the late adult life span indicate a gradual decline in performance with age (e.g., Bäckman, 1991; Bäckman & Larsson, 1992; Crook & Larrabee, 1992). There are, however, studies indicating no age differences (e.g., Cohen & Faulkner, 1989; Larsson & Bäckman, 1993; Olofsson & Bäckman, 1993). With reference to the previous discussion on potential impacts of health-related factors on cognitive performance, it is important to note that a careful health screening has not been performed in these memory and aging studies. This may be an essential factor underlying the contradictory findings. In studies performed by Wahlin and colleagues (e.g., Bäckman & Wahlin, 1995; Wahlin et al., 1993, 1995), careful health screening was routinely performed. The outcome of these studies showed that performance in a variety of episodic memory tasks differs reliably in comparing elderly people between 75 and 96 years of age. This was the case in tests of episodic face recognition, free recall and recognition of random word lists, and free and cued recall of organizable words. The age-related differences were, however, relatively small in raw score numbers and more pronounced in the free recall tasks as compared to the recognition tasks. In a study of 1000 healthy participants ranging in age between 35 and 80 years, a battery of episodic and semantic memory tests (Nyberg, Bäckman, Erngrund, Olofsson, & Nilsson, 1996) was employed. It was found that after controlling for differences in demographic (education, gender), cognitive (visuospatial ability), and health-related (blood pressure, serum vitamin B^{12}) factors, age did not predict performance on tests of semantic memory. The impact of age on tests of episodic memory was substantially reduced when differences in the background factors were controlled for, although still significant. These authors proposed that the failure to account for the age effects on episodic memory is because it can be attributed to age-related neuronal changes.

7.02.3.1.4 Memory tests and cognitive support

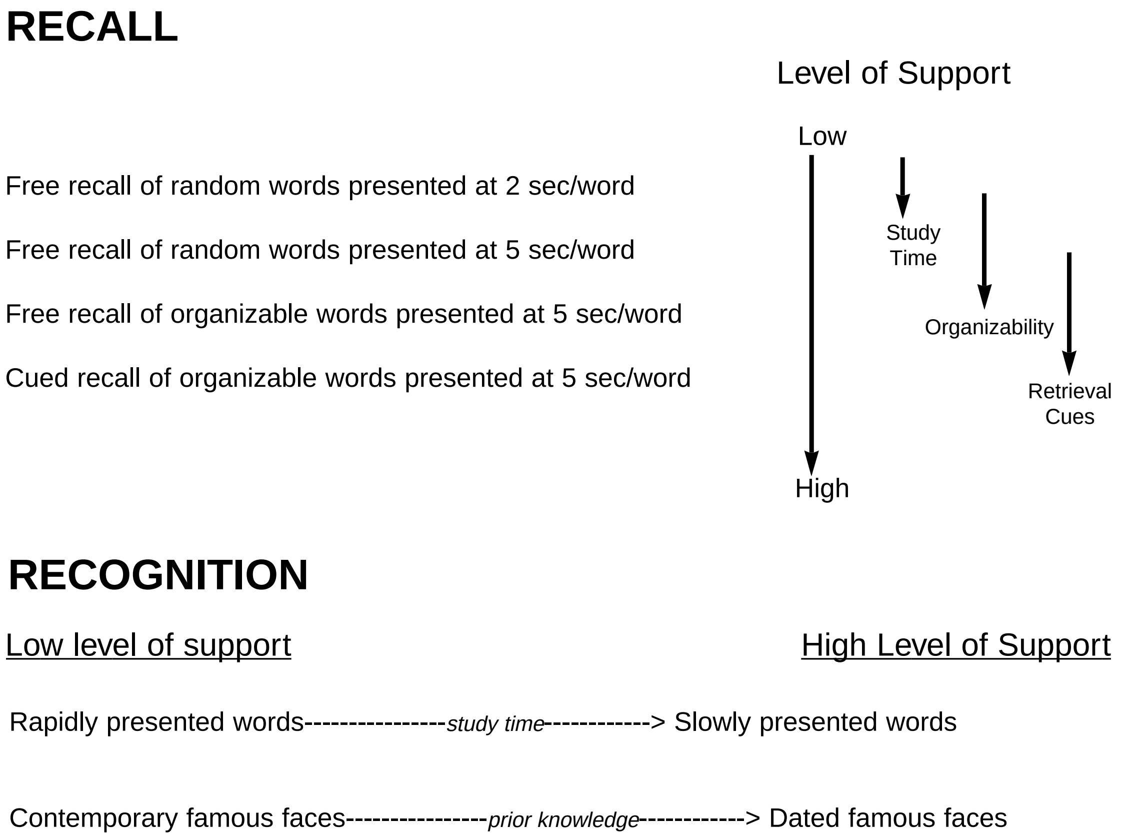
In addition to the many influences on cognitive and memory performance described in previous sections, performance may also vary depending on level of support provided. Some research indicates that age differences are large in unsupported tasks such as free recall, while relatively small in more supported tasks such as recognition (Craik & Jennings, 1992).

Before elaborating on the concept of cognitive support, this subsection will briefly describe three types of memory tests that have dominated research on episodic memory. In these tests, the retrieval conditions vary, such that free recall represents the lowest level of support, cued recall represents a more supportive test condition, and recognition of the information to-be-remembered (TBR) is the most supportive retrieval condition.

In the free recall task, subjects are presented with the items and are then asked to recall without prompting what was previously presented. In the cued recall condition, cues of some sort are provided by the examiner, and test materials are then typically organizable in some way. Questions such as "what animals do you remember?" or "what kind of furniture do you remember?" constitute the cues. Finally, in the recognition tasks, the initially presented materials are presented intermixed with a number of distractors. Subjects are asked to state whether they recognize items from the presentation.

Tasks may also vary in terms of presentation rate, where a slow presentation rate represents a more supportive condition as compared to a rapid presentation rate. Performance is also dependent upon the nature of the TBR materials. It is well known that stimulus dimensions like modality (i.e., items may be presented in a way that one or more of the sensory systems are stimulated during encoding), richness (e.g., items may be presented as objects or words), and organizability (i.e., it may or may not be possible to combine items in a meaningful fashion) are important to goodness of remembering (see Bäckman, Mäntylä, & Herlitz, 1990). Further examples include the datedness of the TBR materials (e.g., items may be faces of persons who were famous 50 years ago or faces of persons who attained their fame recently). There is a consensus that performance of older adults is facilitated by increasing the support with respect to modality, richness, organizability, and prior knowledge (Bäckman et al., 1990; Craik & Jennings, 1992) (see Figure 4).

There is converging evidence from experimental research and intervention studies that episodic memory in normal aging is modifiable (Bäckman et al., 1990; Verhaeghen, Marcoen, & Goossens, 1992). Older adults possess a substantial cognitive reserve capacity, although it seems to be less than for younger individuals (e.g., Baltes & Kliegl, 1992). However, there is no evidence for a simple relationship among cognitive support, episodic memory, and age (see Bäckman, 1995). Also, the level of support needed for the optimization of memory performance in dementia differs considerably from that required of healthy elderly people. While in dementia, support is needed at both encoding and retrieval, normally aged adults seem to require support at either encoding or retrieval only in order to enhance their performance (e.g., Herlitz, Lipinska, & Bäckman, 1992).



RECALL

Figure 4 Memory tasks ordered along a continuum of cognitive support.

7.02.3.1.5 Summary

Learning and memory are highly interrelated and cannot be fully understood independently of each other. Most studies on memory in aging are cross-sectional and there is typically a lack of information necessary for ruling out the influence of the health status of the participants. The system model of memory employed in recent research usually distinguishes between episodic, semantic, primary, and working memory. Memory performance is seen as influenced by numerous properties acting at both encoding and retrieval stages of memory processing. Task properties may generally be recognized in terms of cognitive support (low–high), although there is no evidence of a simple relation between level of support and performance. The relatively few studies on episodic memory performance in very old age portray a gradual decline into the very late stages of the life span.

7.02.3.2 Intellectual Abilities

Learning and memory represent in a sense the input and output stages of information processing, while cognition, in a broad sense, also includes processes involved in the integration and reorganization of aquired knowledge for the sake of matching behavior in an appropriate manner, that is, intelligent behavior. Certain tasks are novel and require the execution of new behavior, while others may be practiced and require less cognitive effort. The outcome of matching task demands and cognitive resources is evaluated in the relative success, or failure, to perform a task whether measured as everyday performance or by cognitive tests. This section concentrates on abilities as expressed in aging and reported in the current literature, more than on the fundamental mechanisms involved in the mental operations necessary for intelligent behavior (see Craik & Salthouse, 1992; Rybash, Hoyer, & Roodin, 1986).

Studies on intelligence and aging have generally aimed at identifying normative patterns of age-related changes in the various ability components. The components are operationalized by the test battery. The following section describes such intelligence and aging patterns, while the next focuses on some of the specific cognitive components involved in intelligent behavior.

7.02.3.2.1 Intelligence and aging

The intelligence test tradition evolved at the beginning of the twentieth century as a differential psychology with focus on interindividual differences in intelligence. Age was recognized early as an important stratification variable in these studies. This psychometric tradition has since provided a basis for our understanding of normative aging and the typical age-related pattern. The most frequently used battery of tests in this research arena, as well as in the clinical setting, is the WAIS (Wechsler, 1955) and later modifications (WAIS-R, Wechsler, 1981) of this battery, encompassing tests of verbal ability (1, Vocabulary; 2, Information; 3, Comprehension), short-term learning and remembering (4, Digit-span forward and backwards), numerical abilities (5, Arithmetic), abstraction and generalizations (6, Similarities), and nonverbal abilities (7, Digit-symbol substitution; 8, Picture arrangement; 9, Picture completion; 10, Block design; 11, Object assembly). Wechsler divided the test battery into two broad categories: "the hold tests" (1, 2, 3, and 6) and "the don't hold tests" (7, 8, 9, 10, and 11) according to their resistance to age.

A number of cross-sectional studies over a broad age range have consistently confirmed the "classic aging pattern" (Botwinick, 1978), in which the verbal tests are identified as the hold tests and the nonverbal or performance tests as the don't hold tests. These findings were largely confirmed in later longitudinal studies, although the magnitude of age-related changes generally were found to be less than previously found by age differences. These design-related differences are intensively discussed in the gerontological literature and have supported the notion of including characteristics of the individual as well as recognizing influences from the sociocultural context when interpreting studies showing age effects.

The classical aging pattern was partly refined in a series of studies by Horn, Catell, and Donaldsson (see Horn, 1982, for an overview) who suggested a dichotomization between crystallized and fluid intelligence. This distinction was assumed to reflect different developmental trends. The label of fluid intelligence (Gf) was attached to basic processes involved in identifying complex relations among stimulus patterns and the drawing of inferences on the basis of comprehending relationships. The tests proposed to measure this broad ability component should not be greatly aided by the breadth of previous knowledge and include tests of logical reasoning and of figural and spatial relations. Crystallized intelligence (Cc) was defined as the cumulative end product of information acquired by the operation of fluid processes through interactions with the environment. The measurement of experience-based crystallized intelligence includes, for example, tests of vocabulary, information or general knowledge, comprehension, and arithmetic (Horn, 1982). The definition leads to expectations of preserved function, or even improvements with age.

The distinction between fluid and crystallized intelligence in aging differentiates intelligence components with regard to age. While development into adulthood is characterized by a differentiation of various abilities it is followed by a dedifferentiation in late adulthood and aging (e.g., Reinert, 1970). The broad categories of fluid and crystallized intelligence correspond to a dedifferentiated pattern of formerly more independent abilities. Some researchers claim that this dedifferentiation continues, and that there remains only a broad component of basic cognitive performance in the oldest old (eg., Marsiske, Lindenberger, & Baltes, 1994). The arguments for a more rudimentary intelligence system in advanced age awaits, however, further empirical support.

Although the results from some studies have been interpreted as favoring the general outcomes predicted by the fluid–crystallized dichotomy, the trend in recent research on intelligence and aging is to examine various intelligence components separately. This is consistent with the interest of a clinican when faced with separate scores for various tests. There are problems inherited in all higher-order approaches to intelligence, for example, the comparability between tests in different batteries. The greatest value, therefore, may be that higher-order approaches to intelligence can serve as heuristic frameworks for the clarification of relationships between complex abilities.

The most informative data on aging and intelligence patterns emerge from longitudinal studies using multiple measurements over longer time periods (see Berg, 1996; Schaie, 1996). In the ongoing H70 study in Gothenburg, Sweden (Rinder, Roupe, Steen, & Svanborg, 1975), a random population-based sample were included at the age of 70 and then followed over the years. Interesting patterns of age-related changes, as well as continuity, emerged. In this study, the effects of tertiary aging (terminal decline) were also examined separately for different survival intervals. That is, trends of change for individuals, for example measured at Time 1, Time 2, and Time 3, and then deceased, were compared with that of individuals who survived into the assessment at the next occasion, that is, Time 4. The main finding in the H70 study was that of a robust and pervasive terminal decline pattern in which performance levels were associated with survival. Figure 5 (a) and (b) (Berg, 1987) show this for a test of verbal meaning (Synonyms; SRB:1, Dureman & Sälde, 1959) and reasoning (Figure logic; SRB: 2, Dureman & Sälde, 1959).

The data from longitudinal studies typically show less change than is the case when examining age differences in cross-sectional studies. Although more accurate in providing a portrayal of intelligence and aging, longitudinal studies are affected by attrition and other selective influences that are likely to produce too optimistic a portrayal of aging trends.

7.02.3.2.2 Specific cognitive abilities

The "top-down" intelligence and aging perspective (described above) is here supplemented with a "bottom-up" approach focusing on specific cognitive abilites and some tests used for the measurement of these abilities.

(i) Speed of behavior: perceptual and psychomotor performance

Speed of behavior is a crucial ingredient in many memory and cognitive tasks because of time constraints, whether it is in everyday life, in the laboratory, or in clinical tests. While it has been argued by some that time is less important than accuracy, and that speeded tasks are unfair to elderly people, others have argued for the inclusion of speed of behavior as an important marker of intelligent behavior. The former position was supported by early assumptions that the reduced rate of processing was extrinsic or peripheral to the primary aging of the nervous system. Slowing has, however, been recognized as an intrinsic phenomenon that accompanies aging (e.g., Salthouse, 1993) caused by increased levels of noise in the nervous system (e.g., Cremer & Zeef, 1987), or broken or attenuated neural connections (MacKay & Burke, 1990). Most reseachers seem to have accepted speed as an inevitable component in various tests of intelligent behavior.

Psychomotor performance was frequently studied in the early days of gerontological inquiries. The prototype experiment compared performance of young and older people on tests of simple and complex reaction time (RT). The results of numerous RT studies consistently show that when the cognitive demands are increased by the introduction of multiple stimuli and response formats, the effects of age become more pronounced (Welford, 1977). The literature on perceptual speed also demonstrates a general agreement on age-related decline.

Attention and decision constitute two highly interwoven components in speed of behavior. Attention has been examined using experimental paradigms for divided and selective attention, vigilance, or the ability to identify less frequent signals occurring over long time periods, or in terms of concentration and search for certain signal patterns within an array of similar signals. Tests like digit-symbol in the WAIS battery represent a way to study concentration and search. The findings from this test demonstrate marked age effects. Elderly people show worse performance in terms of items accomplished per time unit, as compared to younger people. Accuracy is, however, not impaired in the elderly. The trail-making test is a frequently used clinical test for psychomotor performance and attention. Robins Wahlin et al. (1996) administered this test in a healthy sample of individuals aged 76–93. As expected, they found that the time needed to complete the test increased significantly with age. Noteworthy, however, is that they found no age differences in accuracy.

An important message is that lower speed is also related to deficient performance on a number of memory and other cognitive tasks. The pervasiveness of reduced speed of behavior in aging, thus requires that this phenomenon is taken into account in evaluating performance in tasks where speed is an ingredient (Salthouse, 1985; Stankov, 1988).

Studies in which elderly individuals' slower rate of processing is compensated for by elimination of time limits still show an overall pattern of performance decline with age, identical to that found when time constraints are present. The oldest, however, seem to benefit somewhat more from eliminated time limits (e.g., Botwinick, 1977; Robins Wahlin et al., 1993), but age and other interindividual differences remain. In everyday life, however, compensatory behaviors become essential for the functioning of the individual. Performance is better when time is less of a restriction.

(ii) Verbal abilities and language

The spontaneous use of language, as in unrestricted speech, typically reveals experience-based learning and thereby cohort differences and other sociodemographic characteristics. That is often evident in the communication across generations where younger and older persons may find themselves using different words, grammar, and syntax. In this sense, language serves as a "generation marker."

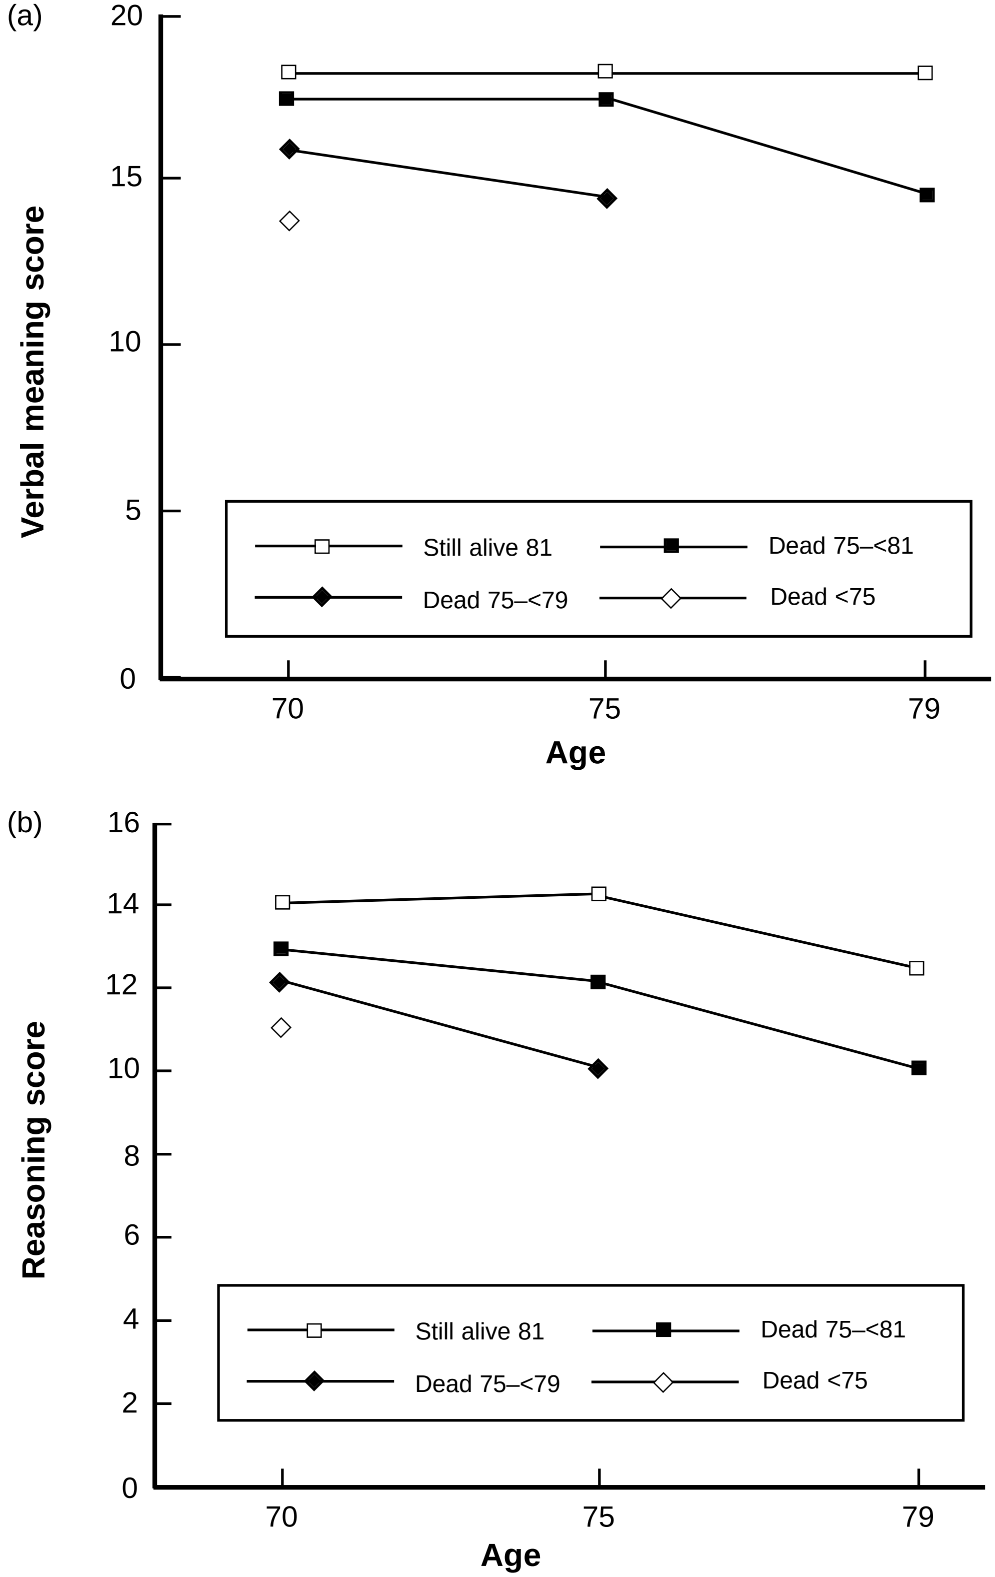

Figure 5 Longitudinal scores for a test of verbal meaning (a) and reasoning (b) showing terminal decline. ("Intelligence and terminal decline" by S. Berg, 1987. In G. L. Maddox and E. W. Busse (Eds.), *Aging: The universal experience* (pp. 414–415), New York: Springer. Copyright 1987 by Springer Publishing Company. Adapted with permission).

Besides speech comprehension, language also involves the domains of reading and writing. All these aspects of language are likely to be affected by sensory problems prevalent in the aged, including difficulties in visual acuity and hearing (presbycusis). In writing, hand motor ability also becomes important. The influences of these peripheral sources of impairment must be considered in evaluating potential cognition-related deficits in language. Despite sensory problems, language abilities are generally well preserved at the level of communication in aging (e.g., Bayles, Kaszniak, & Tomeda 1987). Furthermore, certain language difficulties may not become manifest because individuals may compensate for minor difficulties in unrestricted speech. Difficulties can be covered through the use of compensatory strategies, for example, simplifications or pauses filled with "Ums."

Language abilities require components of linguistic and lexical knowledge (vocabulary), word finding, and verbal fluency. The knowledge of linguistic structure, including syntax, seems to be a well-preserved ability in aging. In an extensive study by Emery (1985) on various aspects of language in younger individuals, normal elderly, and elderly individuals with dementia, results indicated that normal elderly people had greater difficulties with more complex syntactic structure. In the demented sample all aspects of language were affected (for details see Emery, 1985).

Vocabulary, or verbal meaning and verbal fluency have been extensively studied and tests of these aspects are often also included in comprehensive batteries. The general findings for vocabulary demonstrate continuity, whereas speeded fluency tests show lower performance in elderly individuals. In this sense, fluency becomes yet another marker of speed of behavior (Obler & Albert, 1985).

The ability of naming has been investigated using the tip-of-the-tongue (TOT) phenomenon. Studies generally show that younger individuals are more advantaged in their access to the lexical network needed for accurate naming of objects (Burke, Mackay, Worthley, & Wade, 1991). The close relationship between accuracy and speed, previously discussed, is also observed in word-finding tasks, where accurate speed tends to become a prerequsite for the primary naming. Difficulties in finding the name of objects may be described as a memory failure by subjects themselves. The literature indeed shows that memory mechanisms are involved in TOTs, although this involvement is more pronounced in the complex usage of language abilities, as for example in discourse (Burke, Worthley, & Martin, 1988).

While relatively robust in primary aging, language and verbal abilities are prone to cerebral lesions in dementia, where the "aphasia-agnosia" syndrome constitutes a diagnostic marker. Available information on various aspects of language are still relatively sparse, compared to other cognitive functions in aging (see Kemper, 1992; Light, 1988).

(iii) Visuospatial and visuoconstructive abilities

The components involved in visuospatial and visuoconstructive abilities include pattern recognition and the understanding of dimensionality. Reading a clock face, telling the time and setting the clock hands on certain times, reading maps and drawing maps represent some ecological examples of this cognitive domain.

The block design test in the WAIS battery is often thought of as a prototype test for visuospatial ability. The results from this test show worse performance in older individuls. Robins Wahlin et al. (1993) used block design and a clock test to study visuospatial functioning and spatial orientation in a healthy sample ranging from 75 to 96 years. In block design, they found significant age differences in which the youngest individuals showed superior performance. Interestingly, the test was administered both in the standard format including fixed time limits and in a format without time limits. The differences across ages remained in the no-time-limit condition, although performance levels were increased. In examining performance for each individual design, they found age effects only for the most complex designs. In the clock test, encompassing the tasks of setting hands on preprinted clock faces and time telling, they also found a slight but significant age effect in both. The oldest, aged 90 to 96 years, were less accurate than individuals in the age range of 75–89 years. It was concluded that there is an age-related deterioration in visuospatial abilities that continues into very old age.

Visuoconstructive tasks include components of perception, motor behavior, and spatial orientation. Such tasks are often included in clinical batteries, for example, in tasks where subjects are asked to copy figures at different levels of complexity. Such tests also provide qualitative information, including type of errors, that may be useful. The findings from studies on visuoconstruction generally show that the copying ability is well preserved in aging when motor and sensory difficulties are taken into account (e.g., Van Gorp, Satz, & Mirushina, 1990).

(iv) Problem solving and executive functions

A complex domain of cognitive functioning involves problem solving and logical reasoning, including inductive as well as deductive components. Problem solving encompasses all behaviors executed when facing old problems that we have learned how to solve, as well as novel problems requiring reorganization of already established modes of thinking and acting. Problem solving includes concrete as well as abstract thinking, and therefore constitutes a broad category of intelligent behavior.

Various tests of reasoning and problem solving are often included as subtests in comprehensive test batteries. For example, in Schaie's longitudinal Seattle study (Schaie, 1995), estimates of age changes in reasoning show a general decline with age. A more marked decline was found for those in their late sixties. This pattern resembles that of other abilities, suggesting that this aspect of problem solving is equally prone to aging as other cognitive abilities. In the Swedish H70 study, inductive reasoning remained remarkably stable across times of measurement in individuals with longer survival. That is, when retrospectively excluding those individuals who died after a certain occasion in the series of measurements, those who survived to the next occasion in the series showed an almost stable performance in reasoning, an ability often considered sensitive to age. This finding suggests that decline is more closely associated with subsequent mortality, rather than with age *per se* (see Berg, 1996, and Figure 5).

A well-known reasoning test is that of Raven's Progressive Matrices (Raven, 1982), including the original and the coloured matrices versions. Subjects are instructed to find a principle among certain patterns and to choose a pattern that corresponds to this principle in identifying a missing pattern. Significant age differences suggest lower performance with age in the original version of the test (see Lezak, 1983, 1995; Salthouse, 1983). This finding was also confirmed in a study by Denney and Heidrich (1990), who interestingly employed a simple training strategy before administering the test. Following training, equal improvements were found for young, middle-aged, and elderly individuals.

Another aspect of intelligent behavior is that of executive functions which refers to abilities that successfully enable a person to engage in "independent, purposive, self-serving behavior" (Lezak, 1983, p. 38). Questions about whether people will execute a certain behavior and if so, how they are doing it, capture the dimension of executive functioning. Lezak (1983) articulated four components of executive activity-related behaviors: goal formulation, planning, carrying out goal-directed plans, and effective performance. Given these components the question arises regarding how to evaluate the aspects of "whether" and "how." The interest in executive functions emerged in neuropsychology and is largely associated with interest in cerebral dysfunction, especially with dementia and frontal lobe lesions (e.g., Moss, Albert, & Kemper, 1992; Shallice & Burgess, 1991)

Symptoms like distractability, passivity and apathy, apraxia, and perseverations, affecting self-care behaviors and leading to impaired activities of daily living have often been the focus. In patients suffering from frontal lobe lesions, impairments become manifest in a more obvious manner. Executive functioning is, however, usually maintained in primary aging although affected by a slower speed of behavior. The complexity of the executive dimension requires close scrutinity of sensory and motor handicaps, and of other noncognitive factors that potentially may influence the individual's adaptation to demands in everyday life as well as performance on cognitive tests (LaRue, 1992).

The generation of alternate behaviors necessary to overcome and compensate for deficits in certain domains can be seen as an indicator of the flexibility aspect of executive functioning. Cognitive flexibility, or the ability to shift strategy in order to solve and overcome certain problems, is an essential component in many tests, as well as in real-life situations. Rigidity, the converse of flexibility, is a more visible marker for the lack of flexibility in the ecological context. Tests that require switching from one strategy to another or tasks in which overlearned responses are to be inhibited in favour of new responses generally show superior performance in younger individuals. The Wisconsin Card Sorting Test (WCST, Grant & Berg, 1948) is another test requiring cognitive flexibility. Subjects are here instructed to organize cards according to different principles, for example, color and form. Only slight age differences were found in a study of healthy, well-educated elderly individuals' performance on a modified WCST version (Haaland, Vranes, Goodwin, & Garry, 1987). The study provides support for the conclusion that executive functions in primary aging remain relatively unaffected.

Although verbal fluency and certain tests of construction and motor performance can serve as markers of executive functioning (Royall, Mahurin, & Gray, 1992; see also Lezak, 1995), noncognitive influences must be taken into account in evaluating performance. A powerful approach for examining executive functioning is the observation of naturalistic behaviors interpreted in the context of previous ability, sensory and motor functioning. An elderly person unwilling or unable to perform as before and exhibiting lower cognitive flexibility has to be assessed in a broad context, including information on coping, perceived personal control, and well-being, before any definite conclusions can be drawn about deficient executive functioning.

7.02.3.2.3 Summary

In the intelligence test tradition, the most frequently used battery is the WAIS. The subtests can be subdivided into "hold tests," assumed to measure crystallized intelligence, and "don't hold tests" measuring fluid abilities. Crystallized abilities are relatively stable across the entire adult age span, and some may improve even into old age. Fluid abilities, on the other hand, are more sensitive to age, as well as to various diseases. The findings of terminal decline (tertiary aging) in cognitive abilities demonstrate the close interrelationships between brain function and vital physiology in aging.

7.02.4 COPING WITH COGNITIVE CHANGE IN AGING: PERSPECTIVES OF THE AGING INDIVIDUAL AND THE GEROPSYCHOLOGIST

Some implications of reported findings on memory and other cognitive aspects of aging will be discussed in this section, including considerations relevant to the geropsychologist.

7.02.4.1 "From Lab to Life"

The research literature on memory and other cognitive functions conveys the general conclusion that decline and change become more likely with advancing age, although the age-related sensitivity differs for various tasks. At the same time we usually find that most elderly people maintain independence and successful functioning in everyday life even though this involves numerous tasks that require complex memory and cognitive abilities. These observations seem contradictory and address questions about the significance of reported findings on memory and cognitive changes in aging, revealed in the experimental or clinical setting. These different portrayals of aging also become evident to the geropsychologist. Salthouse (1983) suggested four explanations for the discrepancy between "lab and life": individual differences, ecological validity, cognitive demands in terms of complexity and difficulty, and everyday life experiences and learning.

7.02.4.1.1 Individual differences

The individual differences issue is a neglected aspect in the prevailing normative tradition in the gerosciences. The use of chronological age, as a proxy marker for aging, and the arithmetic mean as the typical statistic for describing performances, tends to emphasize general patterns over unique features, including that of interindividual differences.

In everyday life we may face individuals in advanced ages who show better performance than they did some years ago. The recovery from certain diseases and treatment effects are also seen in advanced ages. The normative design is, however, unlikely to show both sides of the coin, that is, while some individuals decline, others remain stable or even improve their performance over time. Besides generation and cohort differences, individuals of the same age typically manifest great differences in physical as well as psychological functioning. Elderly people are distributed between the extremes of those who experience early physical and cognitive impairments and, at the other end of the continuum, the successful agers who maintain their performance throughout life. This notion is important because it provides a basic frame of reference for assessment, as well as an accurate portrayal of aging.

An interindividual perspective is an essential element for the geropsychologist. The research literature provides the general norms for late-life functioning, and at best adequate norms for various tests. An assessment requires, however, detailed information about previous functioning of the individual. Such information, or more likely assumptions about "baseline performance" in earlier days, should provide the ultimate points of reference for the geropsychologist.

7.02.4.1.2 Ecological validity

Ecological validity refers to the congruence between laboratory and clinical tests, and everyday life tasks requiring memory and other cognitive resources. Although certain experimental tasks may be considered as esoteric, they surely activate cognitive subprocesses and components of relevance for life outside the laboratory. The overall aim in experimental aging and cognition studies is the understanding of age-related change in those subprocesses and components. In this sense, the complexity of everyday life tasks can never correspond to requirements in the laboratory setting. Although the range of available tests covers many dimensions of memory and cognitive functioning, it is important to remember that they still represent only a sample of markers for various cognitive processes.

Another aspect of ecology relates to compensatory behaviors that tend to be neglected in the laboratory. In everyday life individuals can compensate for weaknesses in certain abilities by profiting from strengths in other areas of functioning. In this sense difficulties may not become manifest in natural settings. In tests, however, individuals are usually inhibited from using compensatory strategies to overcome weaknesses. Impairments are then more likely to be evinced.

The "lab–life dimension" represents an important issue for the geropsychologist when confronted with an individual showing impaired test performance, but demonstrating relatively intact functioning in everyday life. The detection of cognitive problems on certain tests may be due to disease processes (secondary aging) and provide arguments for interventions aimed at retarding or improving performance. Low performance on tests is also indicative of the cognitive expenditure that is needed to manifest "intact" everyday functioning.

7.02.4.1.3 Complex cognitive processing

The notion that cognitive demands in everyday life are less complex and difficult than that of laboratory and clinical tests deserves attention. One might argue that the demands of the two situations are not identical (e.g., Baltes & Willis, 1979). Laboratory and clinical tests of memory and cognition are usually designed in accordance with psychometrics. This means that level of difficulty is deliberately introduced as a variable for evaluating performance. Everyday life is often highly predictable through recurrent tasks and events with which we have learned to cope. Tests of memory and cognition are also likely to introduce novel tasks, requirements, and a setting that is unfamiliar to the individual.

The familiarity with psychological testing differs across age cohorts. The oldest old tend to have fewer such experiences. Recommendations of "age-fairness" should be evaluated against this background. In addition, in real life people tend to seek those environments that fit their interests and available resources, including those that relate to cognition. This is a matching of abilities and task demands that does not occur in the laboratory or in the clinical test situation. In evaluating an individual's performance, geropsychologists have to consider how a task should be presented, how the instructions are administered, including feedback to the individual. Motivation and other noncognitive factors are also important. The importance of instructions and practice before administering a certain task is well known to the experienced clinician. Standard tests and batteries usually allow only brief instructions. Difficulties experienced by elderly people in comprehending these instructions, for example, in abstract tasks, are likely to interfere with later performance. Ensuring that the individual understands task requirements can therefore significantly improve performance (e.g. Baltes, Sowarka & Kliegl, 1989).

7.02.4.1.4 Everyday life experiences and learning

Although research on memory and cognition in aging typically confirms a deterioration view, the resources in most individuals are sufficient to cope with environmental demands of daily life. When the magnitude of decline exceeds the ecological demands it becomes a manifest deficit. For example, in the diagnosis of dementia, the impairment in memory and other cognitive abilities must interfere with daily life functioning according to diagnostic criteria (American Psychiatric Association, 1987, 1994). Many activities and tasks in everyday life are overlearned by their being practiced over and over again. As noted by Salthouse (1983), "since increased age in adulthood is generally positively correlated with experience, many highly practiced activities may be maintained at a constant level despite age-related declines in component ability because of the compensating effects of greater experience" (p. 203).

In experimental and clinical settings, memory and cognitive tasks are typically novel and the cues and instructions provided do not necessarily correspond to those available in natural, everyday life. Performance is then more unlikely to rely on previous experiences. The ability for adequate everyday functioning is also affected by more or less subtle social and cognitive support systems that constitute natural ingredients in daily-life activities (use of a calendar, reminders, and other external aids). In addition, individuals also tend to withdraw from activities that are viewed as too demanding, using excuses such as that they have lost interest (see Baltes's model below). The geropsychologist has to consider and be aware of the mechanisms of the fit between environmental demands and cognitive capabilities of the individual.

7.02.4.1.5 Current knowledge and extralaboratory cognition

As pointed out by Salthouse (1983), and by recent proponents of testing memory and cognition in daily-life contexts (e.g., Willis, 1996), "the greatest hindrance to knowledge about the relationships between laboratory performance and extralaboratory competence is simply lack of detailed information about the nature of real-world activities" (Salthouse, 1983, pp. 203–204). Clearly, more attention needs to be given to the external validity of results obtained in the laboratory or clinical setting. Improved means of evaluating everyday performances constitutes one avenue for this. Much of the literature on aging and cognitive functions can be divided into three parts on the basis of methodology. Research is conducted in the psychometric tradition, in the experimental tradition, or in the ecological tradition. It seems clear that there are possible gains by cross-fertilization between approaches. Indeed such efforts are not absent. One approach includes bringing everyday activities such as television watching into the laboratory (e.g., Stine, Wingfield, & Myers, 1990) for subsequent tests of, for example, memory. Another logical possibility is to perform clinical or laboratory-like tasks in the subject's everyday world. Weber, Brown, and Weldon (1978), conducted such a study where elderly residents in a nursing home were tested on spatial knowledge and memory for scenes and locations in their nursing home. An even broader approach may be warranted, taking into account such things as collaborative support provided by a spouse (Gould & Dixon, 1993; Gould, Trevithick, & Dixon, 1991). On the other hand, proponents of an applied approach aiming at intervention and adjustment of the environment argue that researchers have now developed sufficient understanding of older adults' cognitive systems to make it possible to improve the quality of life for older adults (see Park, 1992). The latter view relies mainly on knowledge about cognitive processes, as well as documented strengths and weaknesses of the elderly in a broader sense.

7.02.4.1.6 Cognitive aging and the individual: an integrative model

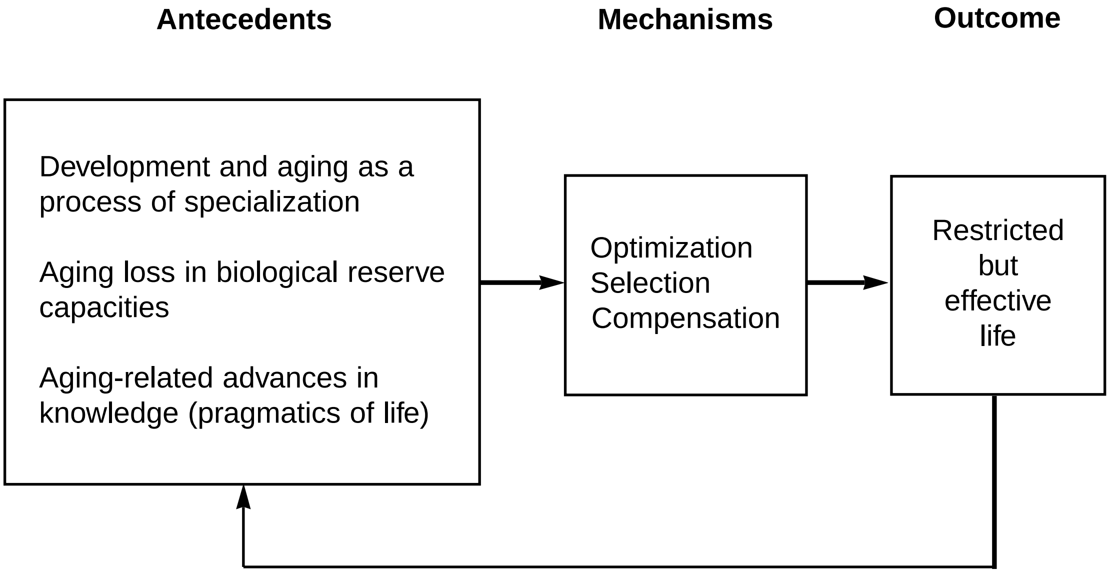
A comprehensive model for the understanding of primary cognitive aging in the real-life context that integrates much of the literature on cognitive aspects of aging was proposed by Baltes (1991). The model (see Figure 6) is based on a series of propositions. These propositions, or general statements, are to some extent already covered in previous sections of the present chapter. Briefly, it is assumed that aging is characterized by much interindividual variability; it is important to distinguish between pathological, normal, and optimal aging; there is much developmental reserve capacity in old age; aging is characterized by a loss of fluid intelligence; knowledge and crystallized abilities may compensate for the losses in fluid abilities; with aging the balance between gains and losses becomes less positive or even negative; and the self in old age continues to be a powerful system of coping and maintaining integrity.

Against the background of these general conclusions, some adaptional mechanisms were suggested for successful psychological aging. The model focuses on the dynamic interplay among selection, optimization, and compensation, all components in a general process of adaption, effective throughout life. However, because of the losses experienced in aging, whether biological, social, or mental, the model is especially applicable to elderly persons. By selection of activities from a previously more extensive repertoire of behaviours, maximizing the effort spent on maintaining certain activities by means of practice or acquisition of new knowledge, and finally fostering of compensatory behavior, performance may be maintained at high levels even in old age.

Without going into details, some conclusions apply to the present chapter. The model has obvious implications for the geropsychologist. In the clinical setting, a wide variety of functions or abilities are routinely tested. Since the purpose of an investigation is usually to arrive at a diagnosis, the focus is often on deficits and weaknesses. Planning for training or rehabilitation, on the other hand, also requires closer examination of strengths and the potential for improvements. However, with reference to the discussion about everyday cognitive performance, it may be justifiable to include a routine for evaluation of cognitive reserves and abilities to adopt compensatory behavior. The impact of interindividual variability is strongly acknowledged in Baltes's model as interindividual variability in old age applies not only to behavioral functioning, but also to indicators of biomedical functioning (Costa & Andres, 1986; Rowe & Kahn, 1987). This variability may in combination with other critical components, such as expertise in some areas, produce differential patterns in aging. Hence, both strengths and weaknesses are equally critical components in a full understanding of the individual's general level of functioning.

7.02.4.1.7 Cognitive reserves and plasticity

Some additional comments on cognitive reserve capacity may be warranted. Following the Baltes (1991) model, potential for cognitive improvement may be discussed in terms of baseline reserve capacity as well as developmental reserve capacity (see Kliegl & Baltes, 1987). Baseline reserve capacity refers to



Antecedents
Mechanisms
Outcome
Development and aging as a process of specialization
Aging loss in biological reserve capacities
Aging-related advances in knowledge (pragmatics of life)
Optimization
Selection
Compensation
Restricted but effective life

Figure 6 Baltes's selective optimization with compensation ("The many faces of human ageing: Toward a psychological culture of old age" by P. B. Baltes, 1991, *Psychological Medicine, 21,* p. 85. Copyright by Cambridge University Press. Adapted with permisssion).

variations in performance due to varying levels of task demands and support, while developmental reserve capacity denotes the range of performance under extended periods of development or practice. Reserve capacity is related to such diverse examples as the acquisition of expertise, testing the limits of an individual's capacity, and memory training.

7.02.4.2 General Assessment Guidelines

Some guidelines in the assessment of elderly persons can be extracted from previous discussions. These general guidelines by no means constitute a complete coverage of all topics. Also, advice in relation to specific diagnostic issues is not dealt with. Certain suggestions are self-evident, but nevertheless important to address explicitly.

Throughout the chapter, it has been emphasized that the level of cognitive functioning is under multifactorial influence and that interindividual variability is substantial in aging. These notions have obvious implications for the geropsychologist. Chronological age has traditionally been the sole stratification variable in the psychometric test tradition. Using test norms to aid in the interpretation of performance ought to be considered in this context. Further, the distinction between primary and secondary aging requires the integration of information from several sources, including that of physical health and social life.

Before meeting the client, we would strongly recommend the geropsychologist to review medical records. Although literature on the relation between cognition and disease is scarce for illnesses in old age other than dementia or major depression, it may be worthwhile to look for the presence of, for example, cardiovascular disease including elevated blood pressure, hyper- or hypothyroidism, diabetes, epilepsy, vitamin deficiency, previous transient ischemic attacks or stroke. The medical literature also lacks, in general, age-graded norms for the elderly, for example, age-adjusted cut-offs for laboratory tests such as the test of folic acid. (For details, see the literature listed in the previous section on secondary aging.)

In the assessment setting it is also strongly recommended to check for vision and hearing. Does the client need certain glasses or a hearing aid? Secure the use of these aids, and, when vision or hearing is poor, consider using adjusted test materials.

Testing should start with a brief interview. During this conversation, much information crucial to later interpretation of test results may be obtained. The geropsychologist should, in addition to basic information concerning education and prior work or career, also collect data about previous and present skills and interests. When necessary, a relative may provide valuable information (e.g., Jorm et al., 1996). The client's general feeling of being in control of daily life as well as beliefs about their own capacity may be informative in evaluating subsequent test performance.

Motivational factors play an important role in the assessment setting. Therefore, one should explain carefully the purpose of the assessment and make sure of the client's comprehension. At this stage, it is possible that the geropsychologist has obtained a clinical impression of the client's general level of functioning. This is important for selecting the relevant tests and for avoiding floor and ceiling effects.

When introducing tests to the client, it may be worthwile to vary task demands systematically in order to investigate reserve capacity. Also, tasks may be varied in terms of time restraints. It is generally advised that tasks be selected in terms of age-fairness.

As noted, in testing older clients, norms are often not entirely reliable. In addition to problems concerning sample selections for these norms, they seldom cover the age range above 80 years. Most studies portray, however, a continuous decline of cognitive performance in the oldest, although performance may remain at relatively high levels. In the absence of norms for the very old and the introduction of other stratification variables than age, it becomes advisable to interpret raw scores carefully.

7.02.4.3 Future Prospects and Cohorts

In the years to come, geropsychologists will meet new cohorts of elderly people who are exposed to other experiences and influences than the elderly people of today. Future clients are likely to require efforts to promote independence and growth in aging, also for aspects of life related to memory and cognition. Future cohorts may require somewhat different diagnostic considerations than today and age-fair testing may refer to something different than today. Improvements in the educational system are likely to exert an impact on performance in new cohorts of elderly people. Furthermore, it may be that successful medical treatments for conditions such as Alzheimer's disease are introduced. In that case, geropsychological expertise may require improved methods for early, preclinical, detection of the disease.

Given increasing interest in geropsychological matters, new test norms adjusted for individuals in the range 80–100 years will hopefully be available to future cohorts of clinicians. The recognition of interindividual differences may end in norms that do not apply chronological age as the sole stratification variable for differentiation within normal and pathological aging. Educational level and gender are two probable candidates among other critical variables to be considered.

The impact of education may seem somewhat far-fetched, as formal education is quite distant in time for elderly people. Education is, however, related to verbal ability and strategy knowledge (e.g., Flavell & Wellman, 1977; Gillund & Perlmutter, 1988), both of which are prerequisites for successful performance on many memory and cognitive tasks.

Norms adjusted for gender are, to a certain extent, already available. Generally, women perform better than men on verbal memory tasks (e.g., Larrabee & Crook, 1993; Schaie & Willis, 1993; Zelinski, Gilewski, & Schaie, 1993). Women also appear to perform at a higher level on face recognition tasks (see Shepherd, 1981, for review). Social (e.g., McKelvie, Standing, St. Jean, & Law, 1993) as well as biological (e.g., Gur et al., 1991) explanations have been proposed for these differences.

Aging research is being conducted around the globe and there is a continuous stream of reports and an increasing wealth of information from the psychological, medical, and social gerosciences. Many projects are designed with an interdisciplinary approach which opens potential for cross-fertilizations and analyses of complex interactions among biological, social, and psychological variables. In cognitive aging research, structural modeling techniques are now applied more often in an effort to identify critical components for successful performance (see Salthouse, 1991). Although, not theory based, the approach truly recognizes the complexity of various aging processes.

The complexity of aging processes becomes apparent for the geropsychologist in the evaluation of performance and gathering of other information in a comprehensive assessment of memory and other cognitive abilities. The challenge is to end up with appropriate conclusions for diagnosis and treatment. For this, geropsychological expertise is indispensable.

7.03.1 INTRODUCTION

The role of social relationships in late-life adaptation has stimulated much social gerontological and psychological research since the 1950s (Cumming & Henry, 1961; Havighurst & Albrecht, 1953; Lee, 1985; Osgood, 1989) and generated considerable debates about theoretical models of social aging. Disengagement theorists, for example, have claimed that social withdrawal reflects an older individual's adaptive response to personal loss and to social forces such as age stereotypes and restrictive social practices (Cumming & Henry, 1961; Maddox, 1963; Pratt & Norris, 1994). Activity theorists, in contrast, have argued that successful adaptation in later life requires older people to be sociall active (Havighurst, Neugarten, & Tobin, 1968; Lemon, Bengtson, & Peterson, 1972). From a life-course perspective, Atchley (1993) stated that individuals in old age prefer those social interactions and social activities that allow for continuity of their life-long roleidentities, experiences, and competencies. Rosow (1975, 1982) claimed that loss of social roles is inevitable in late life and adaptive social aging occurs when older people engage in social activities with age peers. Despite the great diversity in existing theoretical and empirical models of social aging, it has been widely acknowledged that the rules, mechanisms, and functions of social relationships in later life are better understood within a life-span perspective (Antonucci & Akiyama, 1995; Carstensen, 1993a; Marsiske, Lang, Baltes, & Baltes, 1995; Schulz & Rau, 1985). Socioemotional selectivity theory has emphasized and elaborated the role of life-long adaptive and motivational mechanisms that regulate social contact and social relationships (Carstensen, 1987, 1993a, 1995). According to the theory, during early phases of life, preferences for social contacts with others are instigated very frequently by information-seeking goals, yet social contacts in later life are more often determined by emotion-regulatory goals (Carstensen, 1993a, 1995). Empirical findings suggest that older people select and manage their social relationships such that attainment of emotional benefits and emotional goals is maximized or enhanced (Fredrickson & Carstensen, 1991; Lang & Carstensen, 1994; Lang, Staudinger, & Carstensen, in press; Lang & Tesch-Römer, 1993). In addition, structural and functional aspects of social networks appear to follow predictable life course patterns (Antonucci & Akiyama, 1995; Kahn & Antonucci, 1980; Lang & Carstensen, 1994). Social adaptation in later life can also be understood within the framework of the model of selective optimization with compensation (Baltes & Carstensen, 1996, Marsiske et al., 1995). In order to adapt successfully to the constraints of later life, older individuals have to first select meaningful social goals and social resources within the limits of their social-relational contexts. Such selection may then, subsequently, serve compensatory or optimizing purposes in achieving relevant social goals. Compensation, for example, pertains to seeking social support, for example, when adjusting to functional or personal loss. Optimization relates to relational enhancement mechanisms such as generativity or reciprocity (Lang & Baltes, 1997).

Social relationships are dynamic by nature. They vary from person to person, from situation to situation, and from one instance of interaction to the next instance of interaction (e.g., Caspi, Bolger, & Eckenrode, 1987). How adaptive a specific social transaction is thus depends on the situational and relational context as well as on the individual's needs and preferences. For example, a confidant's advice and support to someone who struggles with a decision may be quite supportive and useful during a specific decision-making process but the same advice may be inadequate and even disturbing after the decision has been made. In this example, the adaptive outcome of social contact depends largely on the confidant's empathy and knowledge of the individual's decisional process (e.g., Hogg & Heller, 1990). In more general terms, the adaptivity of social relationships is determined by the extent to which social-relational contexts reflect the individual's social needs and capacities. Such a match between person and context characteristics plays a critical role in understanding the older person's social adaptivity (e.g., Kahn, 1979; Lawton, 1989), and will be discussed in greater detail below.

In this chapter, normative changes in the characteristics of social relationships and social networks across adulthood focusing on close family and friendship relationships are addressed. Then empirical evidence for health-related functions of social support and social relationships underscoring the influence of the older individuals' social needs and preferences in adaptive relational outcomes is reviewed. Next the issue of negative aspects and negative outcomes of social relationships in later life is addressed. Negative aspects of social relationships often have been related to facets of the individual's social relationships, such as ineffective, inadequate, or unpleasant social resources (e.g., Rook & Pietromonaco, 1987) including even physical abuse (Pillemer & Finkelhor, 1988). However, negative aspects of social relationships also may be related to maladaptive social behaviors or characteristics of the older individual such as excessive autonomy needs (e.g., Baltes & Silverberg, 1994) or misanthropy (e.g., Schütze & Lang, 1995). Finally, in Section 7.03.4, findings on the age-, health-, and relation-specific aspects of social relationships are discussed in the light of some more recent theoretical perspectives on individuals' adaptive social behaviors and relational management in later life drawing on socioemotional selectivity theory (Carstensen, 1995) and the convoy model of social relationships (Antonucci & Akiyama, 1995).

7.03.2 AGE-RELATED CHANGES OF SOCIAL-RELATIONAL CONTEXTS

Many changes in the structural or functional characteristics in the social worlds of older people are associated with particular age-specific experiences such as retirement (Bosse, Aldwin, Levenson, Spiro, & Mroczek, 1993; Carp, 1972; Havighurst, Munnichs, Neugarten, & Thomae, 1969) and adult children leaving home, marrying, and eventually having children of their own (Lowenthal, Thurnher, & Chiriboga, 1976; Miller & Cavanaugh, 1990; White & Edwards, 1990). In addition, experiencing the loss of a spouse, close relative, or friend inevitably changes the resources available to the older person (Garrett, 1987; Lopata, 1986; Morgan, 1989). While there is strong evidence that people have fewer social contacts and social relationships in later life as compared to earlier life phases (Gordon & Gaitz, 1976; Harvey & Singleton, 1989; Heller & Mansbach, 1984; Lawton, Moss, & Fulcomer, 1987; Lee & Markides, 1990; Lowenthal et al., 1976; Palmore, 1981), there are also consistent reports suggesting that the majority of old and even very old people are well integrated into family and friendship networks (e.g., Antonucci & Akiyama, 1995; Bowling & Browne, 1991; Levitt, Weber, & Guacci, 1993).

In the United States and in Europe, most older people above 65 years report having 5–15 important or close social partners in their social network (Antonucci & Akiyama, 1987; 1995; Dykstra, 1993; House & Kahn, 1985; Lang & Carstensen, 1994; Lang, Staudinger, & Carstensen, 1996; Stacey-Konnert & Pynoos, 1992). Empirical findings regarding social network size in early and middle adulthood are less consistent but generally range from 15 to 35 network members (e.g., Antonucci & Akiyama, 1994; Carstensen & Lang, in preparation; Van Sonderen, Ormel, Brilman & Van Linden, 1990; Wellman, 1979). Compared to social networks of young or middle-aged adults, older people report a greater percentage of family members and fewer friends or acquaintances in their social networks (Antonucci & Akiyama, 1987; 1995; Babchuk, 1978–79; Levitt et al., 1993; Stacey-Konnert & Pynoos, 1992). Indeed, while many friendships with peers are lost due to death (Garrett, 1987; Johnson & Troll, 1994; Roberto & Stanis, 1994), there is also some indication that older people selectively maintain contacts with close friends rather than less meaningful friends or acquaintances in old age (Bowling & Browne, 1991; Carstensen, 1992; Lang & Carstensen, 1994).

Although the risk of social isolation or feeling lonely may increase in very old age (Larson, 1990; Mullins, Sheppard, & Andersson, 1991), this does not seem to characterize later life phases in general (Revensen & Johnson, 1984; Schultz & Moore, 1988; Shute & Howitt, 1990) and varies across individuals depending on specific relational contexts such as widowhood or marital break-up (Dykstra, 1995; Ferraro & Barresi, 1982; Keith, 1986), marital crisis (Tornstam, 1992), living alone (Henderson, Scott, & Kay, 1986), childlessness (Lang, 1994; Page & Cole, 1991), filial neglect (Connidis & McMullin, 1993; Lang, 1994), or death of close friends (Roberto & Stanis, 1994). Obviously, the social networks of people who are widowed, who have never married, or who are childless differ in many respects from those older people who have lived with their spouse for many decades or who have reared children that have eventually become independent adults (e.g., Connidis & McMullin, 1994; Dykstra, 1993; Lang, 1994). Some older individuals have divorced (e.g., Hammond & Muller, 1992), others have faced the loss of a spouse or close intimates (Dean, Matt, & Wood, 1992; Morgan, 1989), or even an adult child (Moss, Lesher, & Moss, 1986–87; Rubin, 1991–92). The majority of people over 65 years of age have experienced the death of a sibling (Moss & Moss, 1989). Some have focused their social worlds on the maintenance of friendship relationships (Armstrong & Goldsteen, 1990; Johnson & Troll, 1994; Roberto & Scott, 1987), while for others close ties with family members prevail (Field & Minkler, 1988; Field, Minkler, Falk, & Leino, 1993; Johnson & Troll, 1992). Such pervasive multifacetness and heterogeneity in the structure of interpersonal contexts in late life is also reflected in the specific demands and potentials of older peoples' family and friendship relationships.

7.03.2.1 Family Relationships

In general, family relations prove to be reliable and stable sources of social support and social embeddedness in old and very old age, even when relatively little effort is made to keep in touch or to maintain the relationship (Carstensen, 1993b; Crohan & Antonucci, 1989; Field & Minkler, 1993). The close family is most often named as a source of meaningful social contact or social support in old age (Caplan, 1982; Depner & Ingersoll-Dayton, 1985; Dykstra, 1993; Hogan, 1995; Sussman, 1985). Findings from the Berkeley Intergenerational Study have revealed that contacts and feelings of closeness in family relationships are stable or even increase in old age (Field & Minkler, 1988, 1993). This seems to be true for marital relationships and parent–child relationships although less so for sibling relationships (Cicirelli, 1989; Connidis, 1989; Scott, 1990), which are discussed later in this chapter.

7.03.2.1.1 Marriage and intimate relationships

When older people are married or live with an intimate partner, the relationship is mostly described as an important source of meaningful and satisfactory social contact in everyday life (Alwin, Converse, & Martin, 1985; Huyck, 1995). Partners are most often named as social supporters and caregivers when functional losses occur (Brody, 1985; Chappell, 1991; Connidis & McMullin, 1994; Hess & Soldo, 1985). In addition, there is consistent empirical evidence showing that older people are, on average, quite satisfied with their marriages (Brubaker, 1990; Herman, 1994; Levenson, Carstensen, & Gottman, 1993). Later life couples have fewer conflicts and experience more pleasure in sharing intimate and intergenerational experiences or activities than middle-aged couples (Levenson, Carstensen, & Gottman, 1993). Older couples also express more affection than younger couples (Carstensen, Gottman, & Levenson, 1995; Levenson, Carstensen, & Gottman, 1994). Such evidence may also suggest a survival of the fittest marriages, that is, those which have stood the test of time. Moreover, interindividual differences also matter. Empirical evidence suggests that extraversion and neuroticism are associated with marital stability (Cramer, 1993; Kurdek, 1991).

Overall, long-term marital relationships have been demonstrated consistently to be stable and reliable sources of positive and gratifying social experiences. Next to marital relationships, adult children and their families frequently are nominated as the second most important source of emotionally meaningful contact and social support in late life (Chappell, 1991; Dykstra, 1993; Eggebeen, 1992; Hogan, 1995).

7.03.2.1.2 Adult children and grandchildren

Contrary to the popular lore about older parents being abandoned and neglected by their adult children (Shanas, 1980; Steinmetz, 1988), there is considerable empirical evidence showing that adult children not only stay in contact with their parents (Hagestad, 1987), but they continue to share close emotional relationships with them (Field & Minkler, 1988). Frequently they exchange support (Eggebeen & Hogan, 1990; Hogan, 1995; Lang, 1996; Rossi & Rossi, 1990), and are, second only to spouses, the principle caregivers of frail elderly parents (Brody, 1985; Chappell, 1990; Horowitz, 1985; Mancini & Blieszner, 1989).

Typically, older parents also experience the developmental task of grandparenthood that demands the acquisition of a new social role (Kivnick, 1982) and the development of an individual style of grandparenting (Sticker, 1991). Grandparenthood is associated with many changes in the socioemotional worlds of older people such as increased contact and satisfaction with adult children (Aldous, 1987), increase in intergenerational giving (Eggebeen & Hogan, 1990; Tinsely & Parke, 1987), and becoming the keepers of meaning and conveyers of the family tradition (Ramirez-Barranti, 1985; Bengtson, 1985; Hagestad, 1985; Lang & Baltes, 1997). While grandparenthood is often associated with positive experiences and social satisfaction (Kennedy, 1992; Sticker, 1991), grandchildren are rarely named as support providers before they reach early adulthood (Hodgson,1992; Langer, 1990; Markides, Boldt, & Ray, 1986).

7.03.2.1.3 Older siblings

In many ways, social ties with siblings are unique in later adulthood. Older siblings share life-long biographical and historical experiences and are often the only social partners who have known the older individual as a child or adolescent (Cicirelli, 1995; Gold, 1987). Thus, older siblings share an exclusive biographical and sociohistorical knowledge of one another. However, compared to most other close family relationships, social contact frequencies and support exchanges among older siblings are typically limited to times of crises or increased need (Avioli, 1989; Connidis, 1994) unless other intimates such as spouses (O'Bryant, 1988; Wilson, Calsyn, & Orlofsky, 1994) or adult children are unavailable (Connidis & Davis, 1992; Ikels, 1988). As is true for most other social relationships as well, siblings interact more often when they live in close geographical proximity to one another (Connidis & Davis, 1992; Scott, 1983).

However, it is the quality and emotional closeness of sibling relationships that contributes to well-being rather than the quantitative aspects of contact or support exchange (Wilson, Calsyn, & Orlofsky, 1994). These associations are consistently found to be stronger for relationships with sisters or a same-sex sibling as opposed to relationships of sisters with their brothers (Cicirelli, 1989; Connidis, 1989; Pulakos, 1987). Although sibling relationships in later life are often continued sources of conflict and rivalry (Bedford, 1995; Goetting, 1986), older adults may be more discriminating in their choice of social partners in an effort to ensure emotionally gratifying contact with siblings.

7.03.2.2 Friendship Relations

In contrast to social relationships that are legally defined or determined by kinship, friendship is characterized by the voluntary involvement of two or more partners with one another (Adams & Blieszner, 1994; Blau, 1973; Ishii-Kuntz, 1990). Failures to abide by normative expectations in friendships (Roberto & Scott, 1986a, 1986b) in contrast to parent–child relationships, for example, leads to dissolution of the friendship. In addition, longitudinal findings suggest that while the relevance of family roles remains quite stable in old age, the significance of other social roles seems to decrease (Field & Minkler, 1993; Lehr & Minnemann, 1987). Some friendships dissipate and those that remain consist predominantly of friends who have known each other for a relatively long period of time (e.g., Lowenthal, Thurnher, & Chiriboga, 1976).

Notably, friendship relationships have been shown consistently to be associated with higher social satisfaction than relationships with family members who are not living in the same household (Chappell & Badger, 1989; Larson, Mannell, & Zuzanek, 1986, Mullins & Mushel, 1992). One possible explanation for this is that friends are often discharged from tasks that are related to instrumental support exchange and, thus, are less likely to be burdened by caregiving than are family members. In contrast, friends are often named as confidants of old people (Keith, Hill, Goudy, & Powers, 1984; Strain & Chappell, 1982) and are associated with pleasant interactions such as social companionship (Crohan & Antonucci, 1989; Rawlins, 1992). In this respect, friends might play a moderating role in older people's social networks by counterbalancing sometimes difficult or strained family relationships (Johnson, 1983) and by providing opportunities for social integration in the community (Peters & Kaiser, 1985).

When it comes to supportive transactions among friends, satisfaction with friendship is associated with the perceived equity of the exchange (Roberto, 1989; Roberto & Scott, 1986a; Rook, 1989). Nonreciprocal exchanges among friends seem to have even more detrimental effects than among family members (Antonucci & Jackson, 1990). Interestingly, though, close or "best" friends appear to be exceptions (Armstrong & Goldsteen, 1990). Older individuals who reflect their best friends' needs and welfare in their thinking (i.e., communal orientation) report greater satisfaction with their friendships than those who focus on the equity or comparibility of exchanged benefits with their friends (i.e., exchange orientation; Jones & Vaughan, 1990).

In sum, friendship and family relationships are associated with distinct social resources and specific functions that cannot be easily substituted for one another (Litwak, 1985). However, there is also evidence that when specific types of relationships such as spouse or children are unavailable, other relatives or friends appear to assume their functions (Cantor, 1979; Chatters, Taylor, & Jackson, 1986). In general, there is much evidence that older people are satisfied with both their family relationships and their friendships (Field & Minkler, 1988; Herzog & Rodgers, 1981; Ryff, 1989).

7.03.3 HEALTH-RELATED ASPECTS OF SOCIAL RELATIONSHIPS

There is widespread agreement that social relationships provide a fundamental resource for late-life adaptation. However, the underlying mechanisms and health functions of social resources are not fully understood (House, Umberson, & Landis, 1988). Social support has been proposed generally to exert a direct protective effect on health or well-being, while stressor-specific support of others may operate as a buffer when adverse or stressful events occur (Cohen & Wills, 1985; Schwarzer & Leppin, 1991). Others have proposed more complex patterns of associations in which specific types of social resources—such as emotional, instrumental, or tangible support (Rook & Pietromonaco, 1987)—are expected to have specific effects on health or well-being for specific individuals in specific situations (Gottlieb, 1983; House & Kahn, 1985; House et al., 1988; Kessler & McLeod, 1985). However, the age-specific needs and capacities of older support recipients and their social partners are often not well integrated in theoretical models of adaptivity in later life (see also Baltes & Carstensen, 1996; Carstensen & Lang, 1997; Staudinger, Marsiske, & Baltes, 1995). Indeed, considerable empirical evidence may serve to underscore the notion that age-specific social preferences and social belief systems (e.g., social self-efficacy; Lang, Featherman, & Nesselroade, in press) contribute to the adaptive functions of social support and social contact in later life.

The most convincing evidence for positive effects of social support and social networks on health comes from a variety of longitudinal studies of mortality in later life. The interested reader is referred to several excellent reviews of empirical findings about associations of social resources with mortality (Atkins, Kaplan, & Toshima, 1992; Schwarzer & Leppin, 1991), physical health (Antonucci & Jackson, 1987;

Schwarzer & Leppin, 1991), immunologic functioning (Antonucci & Jackson, 1987; Kennedy, Kiecolt-Glaser, & Glaser, 1990), disease course (Kriegsman, Penninx, & van Eijk, 1995), recovery from illness (Reifman, 1995), adjustment to cancer (Helgeson & Cohen, 1996), depression and mental health (Gotlib & Whiffen, 1992; Schwarzer & Leppin, 1992), and well-being (Bowling, 1994; Kessler & McLeod, 1985). It should be noted, however, that some reviews have reported minimal or even no impact of social support on health or well-being (Ganster & Victor, 1988; Schulz & Rau, 1985; Wallston, Alagna, DeVellis, & DeVellis, 1983) and some have also pointed to the potential negative effects of social relationships (Rook, 1984; Rook & Pietromonaco, 1987). In the following, health effects of social relationships are distinguished as they pertain to the relational contexts of older people, on the one hand, and as they pertain to relational behaviors, on the other, such as older individuals' styles or strategies of relating to others, such as selecting social partners, relying on others, reciprocating support, and enhancing social relationships.

7.03.3.1 Social Relationships and Health: Evidence for Positive Effects

Epidemiological studies in the United States and Europe have consistently found associations between the individual's risk of premature mortality and social resources or social contexts. For example, having close confidants or intimate social partners has been found repeatedly to be associated with increased longevity (Berkman, 1985; Berkman & Syme, 1979; Broadhead et al., 1983; Hammer, 1983; Hanson, Isacsson, Janzon, & Lindell, 1990; Orth-Gomer & Johnson, 1987; Steinbach, 1992; Sugisawa, Liang, & Liu, 1994). In the Terman Gifted Study, having a stable long-term marriage predicted increased longevity above and beyond gender, childhood personality, and health behaviors, while the risk of premature mortality was highest among those who had experienced divorce or separation before age 40 (Friedman et al., 1995). Separation and divorce are critical non-normative life events that may affect longevity. When individuals do not develop new intimate relationships after separation or divorce, they are at greater risk of premature mortality (Tucker, Friedman, Wingard, & Schwartz, 1996).

Furthermore, increased social network size and frequency of social contacts reduce the risk of mortality (Cohen, Teresi, & Holmes, 1986–87; Olsen, Olsen, Gunner-Svensson, & Waldstrom, 1991). However, social resources seem to affect morbidity differentially, among men and women (Bryant & Rakowski, 1992; Shye, Mullooly, Freeborn, & Pope, 1995). For example, while premature mortality is related to marital status among men (Berkman & Syme, 1979; Schoenbach, Kaplan, Fredman, & Kleinbaum, 1986), womens' chance of survival is better determined by size of social network (Shye et al., 1995), level of social activity, and church attendance (Berkman & Syme, 1979; House, Robbins, & Metzner, 1982).

In an Israeli five-year incidence study on adult men, high family conflict and low spousal support were related to increased risk of angina pectoris (Medalie & Goldbourt, 1976). In a Danish 14-year follow-up study of mortality, the perceived quality of social resources rather than quantitative characteristics of social networks were associated with increased longevity (Olsen et al., 1991). Generally, there is much empirical evidence that the perceived or subjective quality of social support or social contact are associated more strongly with adaptive outcomes than any other aspect or measure of social support (Antonucci & Jackson, 1987; Dunkel-Schetter & Bennett, 1990; Schwarzer & Leppin, 1991). This further underscores the qualification that social relationships are most effective when they are congruent with the individual's competence and social preferences (Carstensen, 1987; Carstensen & Lang, 1997). For example, in old age declines in health status are associated with receiving help and support from sources that are increasingly distant from the older person (Stoller & Pugliesi, 1988). This means that emotional or instrumental social support may often come from social partners who are not emotionally meaningful to the older person and may thus create unease or enhance feelings of dependence in the older individual.

When changes in health status occur, individuals may change their apprehension of available social relationships and social support (e.g., Gotlib & Whiffen, 1992; Wilcox, Kasl, & Berkman, 1994). When the individual's level of functioning and competence change, the individual may also adjust their preferences for specific social partners and for specific functions of social interactions. However, such changes in social preferences or needs may also affect the adequacy and satisfaction with previously available social resources. Research on social support has often neglected the fact that individuals change their social preferences and social behaviors in the course of physical or mental health crises, even when examined in prospective studies, where social support can be measured before and after health changes occur (e.g., Holahan, Moos, Holahan, & Brennan, 1995; Wilcox, Kasl, & Berkman, 1994). In fact, the benefits and positive outcomes of receiving social support may depend on the older individual's competence to utilize social resources in adaptive ways (Hansson & Carpenter, 1994; Lang, 1996; Thomae, 1994). Findings from empirical studies of health and well-being that do not consider changes in the individual's social needs and preferences may underestimate the actual impact of social resources.

7.03.3.2 The Negative Side of Social Relationships

Since the early 1980s, the perspective of social relationships as a uniformly positive resource has been challenged by conceptual and empirical work that demonstrates that positive relational outcomes can be neutralized or even reversed by negative aspects of social relationships, such as relational strain (Rook, 1984, 1987a), overprotective or unsolicited support (Thompson & Sobolow-Shubin, 1993a, 1993b), daily relational hassles (Bolger & Kelleher, 1993), and violence or physical abuse (Pillemer & Finkelhor, 1988; Pillemer & Suitor, 1992). Another, often overlooked, source of negative experience in social relationships pertains to the experience or anticipation of personal loss that is relatively common in later life (Garrett, 1987; Lopata, 1986; Morgan, 1989).

While negative aspects of social relationships, in theory, are often exclusively discussed in respect to the social behaviors of others (Rook & Pietromonaco, 1987), empirical studies on negative interactions have often focused exclusively on subjective evaluations of social support to the older individual (e.g., Schuster, Kessler, & Aseltine, 1990). Although an individual's negative relational experiences may be difficult to empirically disentangle from social (dis-)satisfaction or perceived support (in-)adequacy, this is crucial for an understanding of the individual's role in dealing with negative contents of social interactions. How an older individual responds to a specific threat or strain in a concrete social relationship may determine the individual's satisfaction or affect as much as the negative event itself. For example, conflict or friction among spouses may be easily resolved when both partners are satisfied with their marriage but may have detrimental effects and even predict separation when marital satisfaction is low (e.g., Carstensen et al., 1995; Gottman & Levenson, 1992; Levenson et al., 1993).

Most negative aspects of social relationships typical in later life may be associated with intensive emotional turmoil that demands efficient types of affective regulation on the part of the older individual. In the following, four sources of potential negative aspects of social relationships in later life are distinguished. They are: (i) dysfunctional social support, such as undesirable, ineffective, or excessive support; (ii) unpleasant or overdemanding social contact; (iii) violence or neglect; and (iv) anticipation or experience of personal loss of others.

7.03.3.2.1 Dysfunctional social support

While there is convincing empirical evidence that social support does contribute to life quality and well-being in later life, there is also a growing body of empirical studies showing that social relationships not only provide gratification but also entail risks and costs for the individual (for reviews see Jung, 1990; Rook & Pietromonaco, 1987; Shinn, Lehmann, & Wong, 1984). Failures to provide social support have been related to a variety of characteristics of the support process such as undesirable social contact (Cutrona, Cohen, & Igram, 1990; Rose, 1993), lack of empathy and sensitivity (Wortman & Lehman, 1985), grudgingly given support (Coyne, 1976), interpersonal betrayal (Hansson, Jones, & Fletcher, 1990), emotional overinvolvement (Coyne, Wortman, & Lehmann, 1988), overprotection (Thompson & Sobolow-Shubin, 1993a, 1993b), and the reinforcement of dependent behaviors (Baltes, 1995).

Negative aspects of social relationships have been shown consistently to operate relatively independently of personality or situational characteristics (Finch, Okun, Barrera, Zautra, & Reich, 1989). Furthermore, empirical evidence suggests that negative experiences in supportive interactions are more strongly associated with well-being or mental health than perceived positive instances of social support (Finch et al., 1989; Okun, Melichar, & Hill, 1990; Rook, 1984; Schuster et al., 1990). However, there is no consistent evidence that detrimental effects of negative social support are enhanced dramatically in the absence of positive social support (Schuster et al.) or in the presence of negative events (Okun et al., 1990). Typically, negative and positive social interactions are only mildly or not at all correlated (Finch et al.; Okun et al.; Rook, 1984; Shinn et al., 1984). It has been suggested (Schuster et al.; Shinn et al.) that such a dissociation of positive and negative aspects may parallel findings on independence of positive and negative affect (e.g., Watson, Clark, & Tellegen, 1988). However, no study, to the best of our knowledge, has examined the age-differential effects of positive and negative supportive interactions on the experience of positive and negative affect in daily life.

Empirical studies of the experience of negative supportive interactions typically have focused on the individual's subjective experience of such negative interaction. However, it seems plausible that older individuals may have idiosyncratic responses to negative events in their close relationships and may develop individual strategies of avoiding or managing negative aspects of close relationships (e.g., Carstensen et al., 1995). Moreover, many negative aspects of dysfunctional social support may also be related to the older individual's social contacts and social preferences. For example, a failure to communicate wishes or needs may be as much responsible for inefficient or inadequate social support as a social partners' lack of social abilities to "do the right thing" (e.g.,Query & James, 1989). It has also been suggested that individuals do not rely on others when they cannot reciprocate received benefits in order to avoid feelings of shame or guilt (Fisher, Nadler, & Whitcher-Alagna, 1982; Riley & Eckenrode, 1986; Shumaker & Jackson, 1979)

7.03.3.2.2 Unpleasant and demanding social contacts

Conflicts, demands, and criticism are part and parcel of even the best close social relationships and may even increase over time (Rook & Pietromonaco 1987; Antonucci, 1985). In addition, personal relationships are not always stable and reliable but to some extent are also characterized by unpredictability and fluctuations (e.g., Lang, Featherman, & Nesselroade, in press).

Although empirical research on unpleasant and demanding aspects of social relationships in later life remains scarce, there is some evidence that older adults may differ from younger adults in respect to how they react and deal with relational conflict or friction (e.g., Carstensen et al., 1995). Older people may be more skilled in avoiding unpleasant or overly demanding situations with social partners about whom they feel less strongly or positive. For example, it has been shown that lack of equity or reciprocity expectations in older adult's friendships are very likely to lead to dissatisfaction or even dissolution of the relationship (Roberto & Scott, 1986a, 1986b).

There is some evidence that when individuals hold negative views toward others they have a greater risk of premature mortality (Barefoot et al., 1987) and are more vulnerable to depression or other form of negative affect when confronted with demands, criticism, or rejection (Smith, 1992). For example, spouses of depressed partners are less supportive, more critical, hostile, and ambivalent towards their partners (Hautzinger, Linden, & Hoffman, 1982; Ruscher & Gotlib, 1988; for a review, see Gotlib & Hooley, 1988). Personality characteristics and relational styles may thus conjointly influence the way individuals react to unpleasant social encounters (Hansson & Carpenter, 1994). However, although personality characteristics are relatively stable over the life course (Costa & McCrae, 1994), their impact in determining outcomes of social interactions and social adaptation may well change with age and may account for fewer outcomes in later adulthood (Lang et al., in press). In other words, older people may be at greater risk of experiencing negative effects when confronted with unavoidable, unpleasant,or demanding social behaviors of others.

7.03.3.2.3 Violence and neglect: the relational dynamics of caregiving

Violent or neglectful behaviors are the most obvious and dramatic negative aspects of social relationships in later life. In the United States, estimates of incidence of elder abuse range from seven hundred thousand to one million people older than 65 years (Hansson & Carpenter, 1994). Violence or neglect occurs mostly in relationships with social partners who share a household (Pillemer & Finkelhor, 1988). Indeed, social contexts of caregiving children or spouses may be experienced as extremely stressful and frustrating for caregivers as well as older individuals (Franks & Stephens, 1996; Schulz, Tompkins, & Rau, 1988; Walker, Martin, & Jones, 1992). Caregiver stress (for reviews: Pearlin, Mullan, Semple, & Skaff, 1990; Schulz, Visintainer, & Williamson, 1990) has been reported to be associated with increased depression and emotional turmoil (Pruchno, Peters, & Burant, 1995; Townsend & Franks, 1995), social isolation, and the lack of social support (Johnson & Catalano, 1983; George & Gwyther, 1986).

In addition, the relational dynamics of caregiving may lead to further escalation of hostility and aggression in the care receiver as well as in the caregiver. Older individuals who receive care must also come to terms with their lack of autonomy and dependence on the caregiver (Baltes & Silverberg, 1994).

7.03.3.2.4 Anticipation or experience of relational loss

Finally, experiencing the deaths of close friends and relatives is normative in late life

(Holmes & Rahe, 1967; Johnson & Troll, 1994). Most individuals over 65 years have experienced losses of close friends, siblings, or of partners during late life and also struggle with the anticipatory loss of other close social partners (Garrett, 1987; Lopata, 1986; Morgan, 1989).

Despite empirical evidence for the negative impact of widowhood on the social world, however, research suggests a more differentiated perspective on adjustment to widowhood (e.g., Ferraro & Farmer, 1995). Prior to widowhood, many spouses endure extended periods when their partners suffer from severe illness and require considerable care (Bass & Bowman, 1990; Bass, Bowman, & Noelker, 1991; Mullan, 1992). Subsequently, as painful as widowhood may be, it can also entail a sense of relief that the spouse's suffering has finally come to an end and the widowed spouse regains freedom to engage in more pleasant activities.

Due to women's longer life expectancy and the traditional age differences among married couples, widowhood is a normative experience among married women. It is a less common experience for married men. In addition, widowhood seems to be related to gender-differentiated demands and needs. Adjustment to widowhood is more strongly related to social compensation among widows than among widowers (Ferraro & Farmer, 1995). Typically, widows are threatened by financial losses following widowhood, whereas men are at risk if they have difficulties with keeping up an independent household (Umberson, Wortman, & Kessler, 1992). In addition, widowhood is associated with a higher mortality risk for widowers than for widows (Bowling, 1988-89; Bowling & Windsor, 1995).

7.03.3.3 Managing Social Resources

A review of empirical studies on differential effects of positive and negative aspects of supportive relationships on late-life adaptation suggests that positive outcomes of social resources are largely determined by the extent to which social resources actually meet the older individual's social preferences and needs. For example, it has been reported consistently, that perceived adequacy of social support is more strongly associated with adaptive outcomes than any other aspects of social support. However, the cognitive and behavioral strategies in supportive interactions that determine and influence subjective support adequacy are not well understood. Few empirical studies have examined cognitive or behavioral correlates of perceived social support adequacy in adulthood (e.g., Dunkel-Schetter, Folkman, & Lazarus, 1987; Röhrle, 1994) or old age (Seeman & Berkman, 1988), let alone considered age-related changes in motivational or emotional determinants of managing social support. Empirical evidence for changed social preferences towards greater emphasis on emotionally meaningful social contacts in late adulthood (Carstensen, 1995; Fredrickson & Carstensen, 1990) suggests that the adequacy and impact of social contact and social support on well-being in later life depends on emotion-regulatory aspects of social relationships such as emotional closeness (Lang & Carstensen, 1994), intimacy (Babchuk & Anderson,1989), generativity (McAdams, de St. Aubin, & Logan, 1993), functional specificity (Felton & Berry, 1992), and trust (Holmes, 1991; Thomae, 1994). There is also empirical evidence that older people benefit from actively engaging in support-seeking behaviors (Filipp & Aymanns, 1987), and from reciprocating support to others (Jung, 1990; Krause, Herzog, & Baker, 1992; Lang, 1996). Others have focused on the personality characteristics of older people that were shown to be closely associated with increased levels of relational competence (Hansson & Carpenter, 1994) related to the initiation, maintenance, and enhancement of social relationships or relational outcomes (Carpenter, 1993; Mariske et al., 1995). Moreover, feelings of control in salient social roles (such as spouse, parent, or grandparent) have been shown to buffer deleterious effects of stressful life events on life satisfaction (Krause, 1994).

The adaptive management of social resources in later life is also illustrated by empirical evidence for the learned dependency model developed by Baltes and her colleagues (Baltes, 1995; Baltes, Neumann, & Zank, 1994). This line of observational research has revealed that dependent behaviors of older ,nursing home residents are more often positively reinforced by responsiveness and social contact than independent behaviors. Subsequent intervention studies demonstrated that independent behaviors of residents increased when staff members and other social partners were trained to be responsive to independent behaviors (Baltes et al.). The initiation of such dependence-support scripts in nursing home settings has been conceptualized as an adaptive behavioral strategy by which older people regulate and optimize the available resources in their social environment (Baltes, 1995). In this case, relinquishing independence is seen as a "proxy control" strategy where the individual gains control in particular domains of functioning through other persons, thereby exerting an indirect influence over the environment (Bandura, 1982; Baltes, 1995). Proxy control may be an important mechanism by which older individuals can compensate for the loss of primary control and enhance the perceived adequacy of social resources (Heckhausen & Lang, 1996).

Moreover, most personal relationships go through times of conflict or periods of relationship crises that must be mastered if social partners are to maintain their relationships (Antonucci, 1985; Duck, 1986). Successfully managing both the stable and varying, positive, and negative aspects of family ties or friendships is likely to be a fundamental requisite for maintaining social adaptivity throughout adulthood and late life (Lang et al., in press; Marsiske et al., 1995; Morgan, 1990).

7.03.4 THEORETICAL PERSPECTIVES ON THE MANAGEMENT OF SOCIAL RELATIONSHIPS

As people grow old, their social relationships and social networks undergo considerable change as a result of both changing relational contexts in later life as well as changes in the individual's social behaviors and preferences. In this chapter, literature showing age-related changes in relational contexts as well as age-related differences in individuals' social motivations and social contacts has been discussed. In the remainder of this chapter, we will summarize and integrate the emerging picture of normal aging in social relationships and propose a common theoretical framework of socioemotional selectivity and social adaptation. It is concluded that people select, mold, and manage their social relationships in accordance with their needs, preferences, and competencies. However, the extent to which an individual can exert control over their social relationships is constrained by the structural and functional characteristics of their social context.

Greater emphasis has been placed on the individual's goals and behaviors when dealing with others (Baltes & Carstensen, 1996; Carstensen, 1993a, 1995; Marsiske et al., 1995). It has been suggested, for example, that the adaptivity of social interactions does not depend solely on the behaviors and competencies of the individual's social partners but also on the individual's own social behaviors and competence (Hansson & Carpenter, 1994; Marsiske et al., 1995). Older individuals, as much as younger individuals, actively contribute to the positive and negative outcomes of their social relationships by selecting and maintaining relationships with particular social partners as well as influencing the specific social transactions that occur within a given social relationship (Lang & Baltes, in press). Thus, when dealing with others, older individuals actively contribute to the maximization of positive gratification or benefits and minimization of negative experience. For example, older individuals do not just receive social support, they also provide support to other people, often to those people with whom they have close relationships or friendships for many years.

7.03.4.1 Socioemotional Selectivity Theory: Emotion Regulation in Late Life

According to socioemotional selectivity theory (Carstensen, 1987, 1991, 1992, 1993a), basic functions of social interaction, such as regulating desired emotional states and acquiring knowledge about oneself or the world, differ in respect to their relative importance for determining social preferences across the life span. For example, Carstensen (1993a) argues that emotional regulation becomes more important in old age because a more limited future alters the likelihood that long-term goals will be achieved. Hence, emphasis is shifted to achieving short-term goals in the immediate social context that are mostly emotional rather than informational.

Socioemotional selectivity theory provides a theoretical framework in which most of the above-mentioned empirical findings on age-related changes and health-related functions of social relationships can be considered. Older people narrow the breadth of their social lives and social participation in order to intensify their engagement in a narrow range of social functions, focusing on close emotional relationships with peers as well as with younger social partners from whom they derive a sense of meaning in life. Reduced social contact in late life, according to this model, reflects the older individual's changed needs and motivations. Indeed, the profile of empirical findings reviewed suggests that it is not the frequency of social interaction or the number of network partners but rather the quality, emotional meaningfulness, and functional adequacy of enduring close ties that contribute to well-being in late life (Beckman, 1981; Ishii-Kuntz, 1990; Lee & Markides, 1990; Lowenthal & Haven, 1968; Rook, 1984).

7.03.4.2 Social Convoy and Support Efficacy: Maintaining Competence in Late Life

The social convoy model of social relations (Antonucci, 1985, 1990, 1991; Antonucci &

Akiyama, 1987a, 1995; Kahn & Antonucci, 1980) describes a conceptual framework for age-related changes in structural and functional characteristics of social networks. Social convoys serve as a metaphorical illustration of the dynamic and age-related changes in social networks over the life span. Throughout life, individuals construct and maintain social relationships with others who also undergo similar changes in social preferences and social behaviors. This also implies that individuals become increasingly aware of specific strengths and weaknesses of their convoy members over time.

This ever-increasing knowledge base allows people to better select particular social network members for particular functions. In other words, people learn over time who best to turn to when emotional support is needed, which social partners are best able to help with activities of daily living, and who is best suited to help in times of crisis. In short, accumulated expertise about others and about relationship rules grows over a lifetime, further guiding and refining access to potential functions of the social world. Through repeated interactions with others, for example, people learn how to avoid critical or unpleasant issues that could result in conflict or negative outcomes. The importance of social convoys to psychological status may be particularly important in old age when many social structural features of the environment (e.g., work) disappear and self-defining roles (e.g., parent) become less active at an instrumental level.

In addition to the social convoy model, the support-efficacy model of social relationships (Antonucci & Jackson, 1987; Lang, Featherman, & Nesselroade, in press) extends the perspective to the individual's competence and self-efficacy in utilizing social resources. Rather than construing social support as a unidirectional process, the support-efficacy model characterizes social support as a process that depends on the personal characteristics of a target individual and support-giver within a specific social opportunity structure. The support-efficacy model is truly relational in that social support is conceptualized as a social transaction of at least two interaction partners who share a specific relationship. In the support-efficacy model, the support-receiver is considered an active agent in the social support process who exerts influence on when and from whom social support is received. On the one hand, social support can compensate for deficits in competence and thus contribute to the older person's adjustment. For example, Hobfoll (Hobfoll, 1989; Hobfoll & Freedy, 1990) has shown that the more social and personal resources are available, the better older people compensate for age-related losses. On the other hand, relying on social support resources also places specific demands on the older individual such as the normative obligation to reciprocate received supports (Antonucci & Jackson, 1987; Gouldner, 1960; Rook, 1987b; Wentowski, 1981).

7.03.5 CONCLUSIONS AND OUTLOOK

In this chapter, it has been argued that the interplay of changes in relational contexts and relational behaviors in later life may determine negative and positive outcomes of social resources. Thus, social adaptivity in later life depends not just on characteristics of the older individual's relational contexts but also on the older individual's needs and preferences within a given structure of relational opportunities. Negative outcomes of social relationships may be a function of a mismatch between the older individual's relational preferences and individuals' actual relational contexts (Lang & Baltes, in press)

Older individuals contribute actively to the positive and negative outcomes of their social relationships, not only in terms of whom they choose to interact with but also in terms of how they engage in specific relational behaviors. Thus, an older individual may contribute actively to the maximization of positive relational outcomes and the minimization of negative relational outcomes. For example, older individuals are not simply active in help-seeking and solicitation of social support from others (Nadler, 1991), they are also support providers to others with whom they have entertained relationships for many years. Providing social support may be seen as the most pervasive illustration of the individual's active and optimizing role in social relationships. Giving support entails social rewards such as feeling needed, trusted or relied upon by others (Thomae, 1994). This also addresses the transactional nature of social relationships. In most cases, when social partners seek or utilize the older individual's advice or other forms of support, this also conveys some appraisal of the older person's competence and thus contributes to feelings of control and social connectedness. Finally, giving support may also enhance the receiver's willingness to reciprocate support in future and, thus, enhance the stability and closeness of the supportive relationship. In this sense, increasing opportunities for older people to provide social support to other people may also support social functioning in later life.

7.04.1 INTRODUCTION

Historical, societal, and demographic changes have led to the rise of gerontology. This comparatively new science already provides an impressive amount of empirical data, which contradict some common stereotypes of old age and aging. Results include, for example, developmental capacity even in the very old, tremendous interindividual differences, different developmental processes in distinct domains within an individual and the important role individual biography plays in the aging process (Baltes & Baltes, 1990; Birren & Schaie, 1985;

Kruse, 1989; Lehr & Thomae, 1987; Mayer & Baltes, 1996).

It is interesting to note, however, that there is a considerable lack of sound studies on sexuality and aging. The scientific community considers the study of sexual behavior a very difficult task which is fascinating but somewhat unseemly, especially with elderly subjects. This attitude might be caused to some extent by the unconscious resistance of scientists to exploring the sexual secrets of their parents. This problem was precisely described by the comedian Sam Levinson: "When I first found out how babies were born, I couldn't believe it. To think that my mother and father could do such a thing." Then, after a moment's reflection: "My father—maybe: but my mother—never!" (O'Donohue, 1987, p. 69).

This anecdote also reflects the conception of women as almost asexual beings, which might be one reason for the fact that gerontological knowledge about elderly sexuality refers predominantly to males. Since elderly females considerably outnumber males, due to the longer life expectancy of women, this focus on male sexual functioning is especially puzzling. It might mirror the societal "double standard of aging" (Sontag, 1972) which means that older women are perceived as being unattractive and asexual much earlier than men.

Many reviews comment on the myths of geriatric sexuality (O'Donohue, 1987; Spence, 1992). These myths suggest that elderly people are not sexually capable, not desirable, and not desirous. Such societal attitudes and stereotypes have various negative consequences for those who are affected. Mild sexual alterations might lead to panic and severe performance anxiety because they are misinterpreted as the beginning of the unavoidable end of sexuality. Many older people feel guilty or are ashamed because of their ongoing sexual interest and behavior, and this may result in total suppression of any sexual feelings (Renshaw, 1983).

Empirical data show that these attitudes are myths and do not reflect reality. Most elderly people are interested in sex and capable of sexual performance until very old age. Combating these myths, however, has led to the establishment of equally incorrect countermyths (Gatz, 1987). These countermyths almost deny any changes of sexual desire and performance with age. They establish an ideal which is a projection of middle-aged values and can be equally harmful (Thomas, 1982). Rappoport (1977) hints at this problem by saying "All we want from gerontology is eternal youth" (p. 207). Unfortunately, the unsatisfactory database on elderly sexuality provides support for truth in the myth as in the countermyth.

7.04.1.1 Reviews and Surveys

There are numerous review articles on sexuality and aging which seem to outnumber original research reports (e.g., Byers, 1983; Capuzzi, 1982; Corby & Zarit, 1983; Datan & Rodeheaver, 1983; Garza & Dressel, 1983; Genavay, 1982; Hermanova, 1983; Hodson & Skeen, 1994; Kay & Neelley, 1982; Kellett, 1993; Kirkpatrick, 1980, Laws, 1980; Libman, 1989; Ludeman, 1981; Luria & Meade, 1984; O'Donohue, 1987; Renshaw, 1983; Robinson, 1983; Starr, 1985; Sviland, 1981; Traupmann, 1984; Turner & Adams, 1983; Von Sydow, 1992a; Weg, 1983; Weiler, 1981; White, 1982). These authors usually review results of the most important studies, which were conducted in the USA and will be described in the following.

Alfred C. Kinsey and his colleagues interviewed 17 500 men and women (Kinsey, Pomeroy & Martin, 1948; Institute for Sex Research, 1953). Their sample was not representative but this was the first study to investigate sexual behaviors from childhood to old age, and it therefore represented a remarkable first attempt to understand human sexual behaviors. Cross-sectional data were collected with structured and standardized interviews. Unfortunately, only 126 males and 56 females over 60 were included in the study, and only 10 females were over 70. More recently, a new report from the Kinsey institute was published which described data gathered in 1970 from extensive interviews with more than 3000 men and women (Klassen, Williams, & Levitt, 1989). This study was restricted to sexual attitudes and did not report data on sexual behaviors.

Other important sources of information are the two Duke University Longitudinal Studies. These results are also rather old, but still very valuable, because they are the only ones which stem from longitudinal data (George & Weiler, 1981; Pfeiffer, Verwoerdt, & Wang 1968; Verwoerdt, Pfeiffer, & Wang, 1969a, 1969b). In the first study, data on sexuality were collected as part of a medical interview, and in the second study a self-administered questionnaire was used. Neither sample was representative (Weiler, 1981). Over the three measures of the first Duke Longitudinal Study the number of subjects aged over 60 declined from 254 to 126 (Verwoerdt et al., 1969a, 1969b). In the second Duke Longitudinal Study a sample of 502 men and women aged 46–71 years was drawn; 348 persons completed all four waves of data collection, but data were only reported about those 278 subjects who remained married throughout the study. Forty-eight subjects were older than 66 years at the beginning of the six-year inquiry (George & Weiler, 1981).

Most of the above mentioned reviews could not discuss the results of the more recent studies (Brecher, 1984; Janus & Janus, 1993; Laumann, Gagnon, Michael, & Michels, 1994; Starr & Weiner, 1981). Starr and Weiner (1981) investigated 800 subjects over 60 in senior centers who attended lectures on sexuality and aging. Of the 4246 subjects who participated in the Consumer Union survey, 2622 subjects were over age 60. Subjects were a self-selected sample of readers of the Consumer Report (Brecher, 1984). Janus and Janus (1993) investigated 2765 subjects with questionnaires "distributed to subjects at a wide variety of sites" (p. 3) in a cross-sectional study between 1988 and 1992; 441 of the subjects were older than 65. The samples of these three studies were also not representative. In a very carefully designed study with a representative sample Laumann et al. (1994) collected 3432 questionnaires about sexual practices in the USA. Unfortunately, they only included subjects aged between 18 and 59.

European studies are not very often reported in the US literature because they are rarely translated. Consequently, the considerable differences between results of US and European studies are not discussed (Von Sydow, 1992a). The following non-American studies are published in English. Persson (1980) selected a representative sample of 70-year-old people in Gothenburg, Sweden. Subjects were invited to take part in a health control, 85% accepted, and 166 men and 266 women were interviewed. Bergström-Walan and Nielsen (1990) drew a random sample of citizens aged 60–80 of Stockholm, Sweden. They mailed 1574 questionnaires, and 509 were returned. Antonovsky, Sadowsky, and Maoz (1990) interviewed 177 men and 121 women from a nonrepresentative sample in Israel. Data included current sexual activities and retrospective reports about past sexual experience.

Taken together, epidemiological knowledge on sexuality and aging is grounded on rather few studies. The database for men is somewhat better, because there are some studies on male sexual behavior only (e.g., Mulligan & Moss, 1991; Schiavi, 1990; Weizmann & Hart, 1987). White (1982) cited 10 studies which investigated exclusively males, while only three studies exclusively focused on females. The following section will briefly review the major epidemiological results on sexual activities. Data are extremely heterogeneous and therefore very difficult to interpret. Some scientific objections against uncautious generalization of available data will be raised.

7.04.2 EPIDEMIOLOGY

7.04.2.1 Sexual Behavior of Elderly Females

Studies in the USA have shown that 70–90% of females aged between 60 and 90 were sexually active (Adams & Turner, 1985; Brecher, 1984; Starr & Weiner, 1981). Sexual activity in these studies referred to intercourse and masturbation. German studies reported, however, that 45%–55% of females aged 50 to 60 were sexually active, and up to 3% of women over 70 years (Tümmers, 1976; Weissbach-Rieger & Franke 1987a; 1987b; Wickert, 1983).

Data on activity in sexual intercourse varied between 15 and 90% for women aged 50 to 59, and between 0 and 66% for women older than 70 years. Frequency of intercourse was reported between once a week and once per month, with a decline with age (Bergström-Walan & Nielsen, 1990; Brecher, 1984; Christenson & Johnson, 1973; George & Weiler, 1981; Janus & Janus, 1993; Institute for Sex Research, 1953; Pfeiffer, Verwoerdt, & Davis, 1972; Starr & Weiner, 1981). Bretschneider and McCoy (1988) investigated very old subjects between 80 and 102 with an average of 86.1 years; of the interviewed women, 70% no longer had intercourse.

Of women over 50 years, 10–50% masturbated, and between 0 and 49% females over 70 years reported this activity. Masturbation was reported much more frequently in US than in European studies (Adams & Turner, 1985; Aresin, 1980; Bergström-Walan & Nielsen, 1990; Brecher, 1984; Bretschneider & McCoy, 1988; Institute for Sex Research, 1953; Schneider, 1980; Starr & Weiner, 1981).

Questions about sexual enjoyment or achieving orgasm were rare. Of women in all age groups, 9–26% reported that they never achieved orgasm (Hite, 1976; Institute for Sex Research, 1953; Janus & Janus, 1993; Laumann et al., 1994). Studies about elderly females revealed that about 70% of the American subjects reported sexual enjoyment but only 20% of subjects aged over 80 (Brecher, 1984; Starr & Weiner, 1981). In an Israeli sample, 43% of women over 65 reported that they were not very satisfied. Of these subjects, 14% recalled that they were not very satisfied between 20 and 30 years, and 28% were not very satisfied in their fifties (Antonovsky et al., 1990). The rate of women who never or rarely reacted with orgasm remained stable at roughly 21% between 40 and 59 years (Laumann et al., 1994) but seemed to increase over 70 years (Bergström-Walan & Nielsen, 1990; Brecher, 1984).

Between 4 and 19% of the subjects reported that they had homosexual contacts at least once in their life and 1–5% stated an ongoing relationship (Adams & Turner, 1985; Brecher, 1984, Hagstad & Janson, 1984). Data from a representative study of subjects aged between 18 and 59 years showed that 4% had same-gender sex partners, 1.3% during the last year (Laumann et al., 1994).

7.04.2.2 Sexual Behavior of Elderly Males

Between 60% and 90% of men aged over 60 and between 48% and 79% over 70 report being sexual active. Over 80% of men in their sixties and 75% in their seventies reported a strong or moderate interest in sex (Brecher, 1984; Pfeiffer, Verwoerdt & Wang, 1968; Verwoerdt et al., 1969a, 1969b).

Between 64% and 89% of men aged over 60 reported having sexual intercourse, with 24%–69% reporting weekly or higher frequency sexual intercourse (Antonovsky et al., 1990; Bergström-Walan & Nielsen, 1990; Brecher, 1984; Janus & Janus, 1993; Weizmann & Hart, 1987). Between 46 and 62% of men over 70 years reported having intercourse (Brecher, 1984; Bretschneider & McCoy, 1988; Persson, 1980).

Between 45 and 59% of elderly males reported that they never masturbate, and 28%–44% reported masturbating at least weekly (Bergström-Walan, 1990; Brecher, 1984; Janus & Janus, 1993; Weizmann & Hart, 1987).

There seems to be a decline in orgasm with age in men. Janus and Janus (1993) reported that 77% of men between age 51 and 64 always experienced orgasm, but only 55% over age 65. Mulligan and Moss (1991) claimed that ability to experience orgasm declined from 61% in the 60–69 year olds to 21% in men aged over 90. Brecher (1984) reported that 85% of men in their sixties and 70% in their seventies always reached orgasm. In comparison, an average of 8% of men between 18 and 59 years were unable to experience orgasm (Laumann et al., 1994).

7.04.2.3 Critique of Epidemiological Studies

7.04.2.3.1 Methodological problems

(i) Sample

There are hardly any representative studies and samples are often very small. Taken together, our knowledge on sexuality and aging is based on roughly 7000 subjects. Discrepancies between European and US data cannot be interpreted because of small sample sizes. Furthermore, the age of subjects ranges between 60 and 100 years, spanning 40 years. This means that sample sizes (e.g., for 60 and 80 years olds) become extremely small for different age groups. From a gerontological perspective, 60-year-old subjects differ markedly from 80-year-olds.

Relying on epidemiological data which stem from nonrepresentative samples can be very misleading. Greeley (1994) compared results from Janus and Janus (1993) with data from the General Social Survey (GSS), which was based on a national household probability sample. The comparison was made about percentages of people having sex at least once a week. Janus and Janus (1993) reported that 81% of men aged between 51 and 64 and 69% of men over 65 had sex at least once a week. The GSS data claimed only 43% of men between age 51 and 64, and 17% over 65 had sex at least once a week. For women, Janus and Janus (1993) reported that 65% aged between 51 and 64 and 74% over 65 had sex at least once a week. GSS results showed that 25% of women between 51 and 64, and 6% over 65 had sex that often (Greeley, 1994, cited in Laumann et al., 1994).

(ii) Research design

Most of the studies used a cross-sectional design. Longitudinal designs are essential, however, to describe intra-individual changes. Cross-sectional data are very often interpreted as if they are longitudinal (Institute for Sex Research, 1953; Kinsey et al., 1948). George and Weiler (1981) reported from their longitudinal study that sexual behavior was remarkably stable over the six years of their study. Their data suggested that differences between age-groups reflected cohort-related rather than age-related effects. Liberation of sexual moral attitudes or changes in age-related stereotypes may even enhance cohort differences in the future.

(iii) Data collection

Most studies used questionnaires or standardized interviews. These methods assume that the meaning of questions will be the same for respondents and scientists. Von Sydow (1992b) conducted an interview study with 91 females and found that seven did not know the term orgasm. Five other women of this sample claimed that a woman needs to have an orgasm in order to become pregnant. Finally, the important Duke longitudinal study (George & Weiler, 1981; Pfeiffer et al. 1968; Verwoerdt et al., 1969a, 1969b) collected data on general medical problems. The medical context for exploring sexuality may not support open answers about sex, especially with many subjects suffering from chronic illness. Furthermore, structured interviews in the first study were conducted by male interviewers which may have caused some reluctance to self-disclose among older women in the 1950s (Pfeiffer & Davis, 1972; Starr, 1985; Verwoerdt et al., 1969a, 1969b).

7.04.2.3.2 Theoretical problems

Every study on human sexuality shows that men are sexually more active than women. This seems to be true for every age group, for intercourse and, especially, for masturbation (Brecher, 1984; Institute for Sex Research, 1953; Janus & Janus, 1993; Kinsey et al., 1948; Klassen et al., 1989; Laumann et al., 1994). Although physiological results indicate higher potency of female response in terms of orgasmic potential in comparison with men (Masters & Johnson, 1966, 1981), women seem not to use this potential. This appears to be particularly true for elderly females and raises the question whether research efforts have met the sexual, social, and psychological reality of older women.

(i) Intercourse

Older widowed women outnumber widowed men approximately 5:1, which means that in basically monogamous societies most women do not have many opportunities for intercourse (Malatesta, Chambless, Pollack, & Cantor, 1988). Therefore, higher frequencies of having intercourse in males do not prove age-related differences of sexual interests between men and women. Pfeiffer and Davis (1972) found that past sexual enjoyment, marital status, and age were significant determinants of female sexual behavior. Antonovsky et al. (1990) reported that marital status alone explained 25% of the variance of sexual activities in women. A representative study of 460 subjects aged over 60 in Germany showed that gender differences diminished when "availability of a partner" was statistically controlled (Brähler & Unger, 1994). Interestingly, investigations of couples revealed that both men and women agreed that they ceased intercourse because of the male (Persson, 1980; Pfeiffer et al., 1968; Von Sydow, 1993).

Differences in intercourse rates for younger age-groups are surprising because theoretically women and men should report the same amount of intercourse altogether. An explanation could be exaggeration of males or understatement of females. Another explanation could be visits to prostitutes by men.

(ii) Orgasm

Examining intercourse ignores information about individual feelings and quality of experience. Men and women can have intercourse without enjoyment or orgasm, but this happens far more often to women than to men (Laumann et al., 1994; Leiblum & Rosen, 1989b; McConaghy, 1993). The fact that important studies did not explore sexual enjoyment or orgasm but focus on intercourse (e.g., George & Weiler, 1981; Pfeiffer, Verwoerdt, & Wang 1969; Verwoerdt et al., 1969a, 1969b) reveals that research has been biased by a male point of view. The occurrence of orgasm would be a clear indicator of satisfying sexual experience and would provide solid ground for the prediction of future sexual interests (Laws, 1980). Fortunately, more recent studies have considered this aspect.

(iii) Interest in sexual activities

Many (male) scientists have investigated interest in intercourse and interpreted their results as representing interest in all sexual activities. Presumably, this has led to invalid results. Studies have shown that, in contrast to men, many women prefer other sexual activities to intercourse, like manual or oral stimulation (Denney, Field, & Quadagno, 1984; Von Sydow, 1993). The clitoris and penis are homologous organs which need stimulation for orgasm. During intercourse the penis is directly, and the clitoris indirectly stimulated. Most women need additional clitoral stimulation to achieve orgasm (Masters & Johnson, 1966; McConaghy, 1993), which explains their preferences. If true gender differences with regard to sexual interests exist they are probably due to different experiences of pleasure and orgasm during the life course (Laws, 1980).

(iv) Sexual experience and relationship

Research efforts have focused heavily on sexual performance and ignored the phenomenology of sexual experiences, namely, the subjective meaning, and relational quality of the experience. Starr (1985) reported that 75% of his subjects aged over 60 indicated that their sexual feelings were as good as or even better than in younger years. They stressed the quality of their sexual experiences instead of quantity. This seems especially true for women for whom the emotional aspect of a sexual relationship are more important than for many men (Luria & Meade, 1984).

Taken together, our knowledge about human sexual behavior and experience in the elderly is sparse. Most of the studies reveal considerable methodological and conceptual weaknesses. Nevertheless, results are often cited and generalized, supporting myths (especially for elderly women) and countermyths on aging and sexuality. Many studies have no theoretical framework. A developmental perspective of aging individuals and couples is clearly lacking in most studies. The following section will focus on physiological changes in healthy elderly people and on psychological aspects of aging and sexuality. Another focus will be on the effects of chronic illnesses on sexual functioning, because the prevalence of chronic illness increases with advancing age.

7.04.3 AGE-RELATED CHANGES IN SEXUAL FUNCTIONING

Most of the epidemiological data suggest that there is a decrease in sexual interest and sexual behavior as one ages. It is often argued that this decline is due to biological changes in sexual response capacity. Age-related biological changes in capacity are difficult to determine because changes in sexual functioning are confounded by the effects of chronic diseases, medication, and cultural expectations. Moreover, Winn and Newton (1982) have documented examples of cultural influences on sexual response capacity. They studied data of the Human Relations Area Files of about 106 preindustrial and traditional societies all over the world. For 28 cultures, data on sexual activities in males were available. In 70% of these societies, older men had little or no reduction in sexual behavior until the age of 75. Twenty-six cultures provided data about female sexuality, and 84% of these data reported continued sexual interest and activity in old females which often included having intercourse with younger men. This study gives some evidence that biological changes do not necessarily lead to a reduction in sexual interest and sexual behavior. Facts about physiological changes will be briefly reviewed in the following. Detailed information is provided by McConaghy (1993), Morley (1991), Sarrel (1990), Schiavi (1990), and Schiavi and Segraves (1995).

7.04.3.1 Physiological Changes

7.04.3.1.1 Physiological changes in females

Menopause is associated with marked hormonal changes, namely, a decrease in estrogen production by the ovaries. There is an ongoing controversy about how the hormonal changes affect female sexuality (for a methodological review and meta-analysis see Myers, 1995). It was thought that decline in sexual activity was related directly to decline in sexual hormones, but estrogen and progesterone levels did not predict women's sexual functioning in the laboratory (Roughan, Kaiser, & Morley, 1993). Estrogen deficiency is responsible, however, for decreased elasticity of the vaginal walls, atrophy of vaginal epithelium, diminished vaginal lubrication, and increased fragility of the vaginal skin (Goldstein & Teng, 1991; Leiblum, 1990; Masters & Johnson, 1966, 1981; Morley, 1991; Morley & Kaiser, 1989; Roughan et al., 1993; Schiavi & Segraves, 1995; Wise, 1989). These changes are probably responsible for coital pain, which is more often reported by postmenopausal women. Estrogen replacement therapy is very successful in treating these vaginal changes.

Although Masters and Johnson (1966, 1981) studied only 11 women aged over 60, their description of physiological changes in healthy women proved to be accurate and their data have been supported by findings from self-report surveys (Bachman & Leiblum, 1991; Dennerstein, Smith, Morse, & Burger, 1994; Hagstad, 1988; McCoy & Davidson, 1985; Morley, 1991). Physiological changes in female sexuality include decreased congestion of the labia minora, decreased separation of the labia majora, decreased vaginal lubrication, decreased orgasmic platform contraction, and occasional painful spastic contractions of the uterus. Furthermore, the breasts become less vasocongested and nipple erection is less likely to occur. Masters and Johnson (1981) reported that aging women require more time in precoital stimulation until lubrication develops sufficiently. Orgasmic duration and intensity may be reduced but the capacity for multiple orgasms remains.

There is some ongoing controversy as to whether women suffer sexual dysfunction following hysterectomy. Bernhard (1986) analyzed 18 studies and detected numerous methodological and measurement problems. Eicher (1994a, 1994b) reviewed research outcomes and concluded that older studies reported negative, and newer studies positive, consequences for female sexuality. He argued that this change is due to better information, sexual behavior advice, and historical changes in attitudes towards sexuality. Results from a recent longitudinal study with 104 women revealed that half of the women reported improvement after surgery and 21% reported poorer sexual functioning. Preoperative sexual activity was the best predictor of postoperative sexuality (Helström, Lundberg, Sörbom, & Bäckström, 1993).

Dennerstein et al. (1994) reported a study with 2001 randomly selected Australian women aged between 45 and 55 years. The natural menopause transition was clearly associated with declining sexual interest, decreased likelihood of intercourse, and increased likelihood of unusual pain during intercourse. Hällström and Samuelsson (1990) reported data from 497 subjects with a male partner who were interviewed twice within seven years. At first interviews, subjects were aged 38, 46, 50, or 54. Of the total sample, 27% reported a decrease in sexual desire and 10% experienced an increase in desire. Age-group differences were marginal. Antonovsky et al. (1990) conducted retrospective interviews with 121 women and 177 men between the ages of 65 and 85. The women reported a marked decrease in sexual desire and sexual satisfaction in comparison to their twenties, thirties, and fifties. McCoy and Davidson (1985) conducted a longitudinal study and reported a significant decrease in coital frequency and sexual thoughts in the postmenopausal compared to the premenopausal period. The decline in coital frequency was related to testosterone rather than to estrogen levels. Sarrel (1982) described sex problems after menopause in 50 couples (e.g., loss of orgasmic response in female partner, erectile difficulties in male partner) who participated in a sex counseling program. Dyspareunia in women was often followed by erectile difficulties in men.

In contradiction to the reviewed data, which support a decline hypothesis, Starr (1985) claimed that "the Starr–Weiner data indicate that women over 60 are more orgasmic than when they were younger" and that "most investigators report that sexual response remains the same or improves after menopause" (Starr, 1985, p. 102). Epidemiological data from a representative cross-sectional study clearly suggested that the number of women who never experience orgasm remained fairly stable until the age of 70 (Laumann et al., 1994). These data do not answer the question, however, whether orgasmic women increase their capacity to orgasm after menopause.

7.04.3.1.2 Physiological changes in males

Men do not undergo a clearly marked, obvious change such as females experience with menopause. Nevertheless, there is a remarkable change in hormone production as well; namely, a decrease in testosterone and bioavailable testosterone in the majority of males (Morley & Kaiser, 1989). Decrease in testosterone production has led to the hypothesis that androgen deficiency contributes to the decline in sexual desire and activity in older men (Schiavi, 1990). Remarkably few studies, however, assessed the role of gonadal hormones on age-related changes.

Schiavi and colleagues investigated 77 healthy, married men aged 45–74 and their partners. The sample was drawn via media announcements. Couples underwent an extensive interview together as well as separately. Data gathering included psychosexual, psychiatric, and marital information as well as a battery of psychological tests. The male subjects were additionally studied in a sleep laboratory for four nights. Electroencephalogram, eye movements, muscle tone, and penile tumescence were monitored. Data revealed that age was negatively correlated with bioavailable testosterone. Bioavailable testosterone showed significant associations with sexual desire, arousal, and activity measures. Furthermore, results showed age-related changes in nocturnal penile tumescence. Frequency, duration, and rigidity of this reaction decreased with increasing age. Finally, age was significantly negatively correlated with sexual desire, sexual arousal, and sexual activity, but there were no age differences in degree of enjoyment of marital sexuality. Increased age was also correlated with erectile difficulties (erectile rigidity, loss of erection during sex) and retarded ejaculation (Schiavi, 1990; Schiavi, Mandeli, & Schreiner-Engel, 1994; Schiavi, Mandeli, Schreiner-Engel, & Chambers, 1991; Schiavi, Schreiner-Engel, White, & Mandeli, 1991).

Masters and Johnson (1981) described four variations in basic sexual physiology in males who were past their mid-fifties. First, it takes longer to achieve full penile engorgement and requires more direct stimulation. Second, there is a reduction of expulsive pressure. Third, there is a reduction of the volume of seminal fluid expelled. Fourth, there is a reduction or loss of ejaculatory demand. Weiss and Mellinger (1990) stated that there are only one or two expulsive contractions of the urethra instead of four major contractions in younger men. Seminal fluid is expelled with less force, which diminishes the sensation of passage through the urethra. There is, rather, a seepage of semen which reduces the intense sensation of ejaculatory inevitability. After ejaculation, the refractory period increases with age. Many men cannot have another erection for 12–24 hours. Further physiological changes include less nipple erection; less, or absence of, flushing of neck, trunk, shoulders, thighs, and forearms; scrotal integument becomes thinner and inelastic; rapid detumescence after orgasm (Weiss & Mellinger, 1990).

7.04.3.2 Psychological Aspects

Modern developmental psychology emphasizes that development is not limited to childhood or youth but continues over the life course. This life-span perspective views development as a product of an interplay between biological, cultural, and psychological influences, that is, individuals interact with their environment continuously over the life course (Baltes, 1987; Baltes, Reese, & Lipsitt, 1980).

Cultural influences change considerably with time. This fact can be illustrated by a closer look at elderly subjects who were investigated, at age 70 in 1980. These subjects were born in 1910. Their parents grew up in the Victorian century. This means that these subjects were exposed to very strict societal norms regarding sexuality during their childhood and adolescence. Masturbation was forbidden and considered to be extremely harmful. Sexual feelings for decent women were unthinkable. Freud's theories and discoveries, especially his description of sexual feelings in children, were regarded as tremendously scandalous in Vienna at the beginning of the century (Freud, 1964). Despite short periods with less restricted sexual norms (e.g., in Berlin during the 1920s), sexuality remained a tabooed, guilt- and shame-laden topic for many years. Considerable changes began with the pioneering work of Kinsey and his colleagues (Institute for Sex Research, 1953; Kinsey et al., 1948) who provided the first published survey of sexual behavior. Masters and Johnson (1966) followed with serious information about "human sexual response." Their work was a breakthrough for the acknowledgment of female sexuality. At the same time the development of the contraceptive pill, the ideas of the hippie movement, and later feminism, contributed to the liberation of sexuality. During the 1980s, the threat of AIDS reduced sexual freedom. The above-mentioned subjects who were 70 years old in 1980 experienced all these influences, but the development of their sexual identity was strongly influenced by Victorian moral standards. The fading of sexuality over ontogenetic time might be, therefore, a product of socialization rather than of biology (Traupmann, 1984).

In addition, cultural influences are very important for age-graded behavior expectations and societal values in general. Modern Western societies are dominated by youth orientation, and sexuality is linked to it. Firm and slim bodies, smooth skin, health, energy, career orientation, money, and luxury are highly valued. All these characteristics are directly or indirectly related to youth, sexual attractiveness, and potency. Elderly people have the difficult task of coping with these societal norms which threaten their self-esteem.

Elderly homosexuals suffer from multiple myths and stereotypes. These stereotypes include that aging gays are oversexed, frustrated, unable to have a lasting relationship, and have an extreme youth orientation (Pope & Schulz, 1990). McDougall (1993) described these myths, and stressed cohort differences between younger and older gays. Elderly gays are used to hiding their sexual preferences, in contrast to younger ones who have benefited more from the gay liberation movement in the 1970s. Cruikshank (1990) reviewed gerontological studies about aging lesbians and gays, and concluded that there were more positive outcomes than expected. Friend (1990) presented a "theory of successful aging" (p. 99) for lesbian and gay individuals. He theorized that the tough lifelong reality with numerous experiences of discrimination leads to the development of a strong ego in gays. They are thus better prepared to cope with the demands and humiliating experiences of aging than the heterosexual elderly.

For women, cultural pressure is particularly damaging because esthetic and erotic feelings in Western societies lead to old women being considered as repulsive (Sontag, 1972). Whereas wrinkles and gray hair are an interesting and attractive sign of experience in men, they are a symbol of decaying beauty and femininity in women. A marriage of an older man and a young woman is a sign of vigor and vitality in the man, but when an older woman marries a young man, it is generally disapproved or even judged as pathological. An illustration of this humiliating experience for women is provided by Thomas Mann. Being himself in his late seventies, he wrote a story about a 50-year-old woman who fell in love with a young man. With his deep psychological understanding of human conflicts he described desire, restriction, and a "betrayal by nature" of this woman (Mann, 1953).

Men also have to face cultural pressures. Male identity and masculinity is directly linked to sexual performance demands. Books, stories, movies, and television shows project a "fantasy model of sex: It's two feet long, hard as steel, and can go all night" (Zilbergeld, 1992, p. 30). The penis is expected to function automatically whenever its owner wishes to use it, regardless of any other conditions. Older men who feel a normal need for more direct stimulation or experience erectile weaknesses can be threatened to the core of their identity. As a 51-year-old man put it: "You want to know how I feel, I'll tell you. I feel like an absolute nothing. I know I can satisfy her in other ways and I do, but that's not the point. I feel like shit, like the center has been taken out of me" (Zilbergeld, 1992, p. 36). Unfortunately, because of this culturally shared fantasy model of male sexuality, many women interpret occasional lack of erection as if they were rejected, not desired, not loved, or not attractive enough. Women have difficulties understanding the intense threat that erectile problems pose for men because they have no parallel experience. The female gender identity will not be questioned by any sexual dysfunction because it is not linked to sexual performance. In addition, women can almost always perform sexually: they can have intercourse without being aroused and can fake enjoyment, but there is no way to fake an erection.

These cultural influences, shared and gender-specific ones, are of considerable importance for psychosocial development and well-being in the elderly (Rosenmayr, 1995). Aging individuals as well as aging couples have to cope with various developmental tasks. Robert Peck (1956) described three phases of development in late adulthood: ego differentiation versus work-role preoccupation, body transcendence versus body preoccupation, and ego transcendence versus ego preoccupation. The first phase refers to coping with retirement. The crucial question is whether a person can derive self-esteem from activities other than work. The second phase means coping with physical decline and health problems. The last stage is very similar to Erikson's (1950) description of ego integrity vs. ego despair as the outcomes of the final developmental task in old age. Acceptance of one's unique life with unchangeable failures and the realization of death are the most important challenges of this stage. These difficult tasks represent a threat to normal narcissism and can have pathological consequences (Eckert, 1984; Liptzin, 1984). Kernberg (1977) described the difference as follows:

> It is part of normal narcissism to love oneself, to be satisfied with one's own appearance, and to wish to be accepted, liked, and loved for what one is. The problem begins when a highly ideal, beautiful and triumphant image of the self linked to childhood or youth becomes an indispensable precondition for self-acceptance and for trusting that one will be accepted by others: this usually reflects a deep devaluation or depreciation of one's self, a sense of loathing and distrust for one's present appearance and value, which can only be compensated for by the eternal looks of triumphant adolescence. (pp. 27–28)

Coping with the narcissistic wounds of aging is a major task for every individual. Fortunately, empirical data indicate that most elderly people manage well and retain positive self-esteem and life satisfaction (Bengtson, Reedy, & Gordon, 1985; Costa et al., 1987; Staudinger, Freund, Linden, & Maas, 1996).

Intimacy and intimate relationships seem to be especially important for coping with the demands of aging (Weiss, 1983, see also Chapter 3, this volume). Intrapsychic changes and role transitions additionally challenge the aging couple. Two examples are marital life after children have left the household, and the retirement of one or both partners. As one woman commented on her stress with the retirement of her husband: "I married my husband for better or for worse, but not for lunch" (Leiblum & Segraves, 1989, p. 377).

Life-span development of gender identity and the concept of androgynization with age has important implications for the individual as well as for the interindividual dynamic of couples and their sexuality (Livson, 1983). Jung (1933) reasoned that role demands in early adulthood require development of selective domains and that older people show greater awareness of aspects of their self which were suppressed earlier. "The man discovers his tender feelings and the woman her sharpness of mind" (p.108).

Colarusso and Nemiroff (1981) theorized that oedipal issues might reawaken because of illness and death of parents. Therefore, internal representations of parents may change and alter the adult's self-concept. This change in personality may also effect sexual feelings insofar that long-standing relationships are higher valued than short-term sexual gratification (Nadelson, 1984).

Finally, aging couples have to face possible dependency of one partner due to chronic illness, and separation through death. Coping with increasing losses of significant others is one of the most difficult tasks for elderly people. Death of the partner means for many traditionally oriented women, besides many other losses, the end of any sexual activity (Malatesta et al., 1988).

7.04.3.3 Health-related Changes

One major problem in examining age-related changes is that the distinction between age-related and health-related changes is almost impossible. Chronic illnesses increase markedly with age and most diseases have a direct or indirect effect on sexual functioning. Thus, it is not aging per se, but comorbid illness that may cause an increase in sexual dysfunction (Schover, 1989, 1992; Spence, 1992). Some authors claim, however, that health aspects tend to be overestimated with regard to sexuality (Fooken, 1994). Common chronic diseases will be briefly reviewed in this section. An excellent overview about geriatric sexuality and chronic diseases is provided by Mooradian (1991). Additional information is given by Burgener and Logan (1989), Gupta (1990), Kaiser (1991), Liptzin (1984), Majerovitz and

Revenson (1994), and Sjögren, Damber, and Liliequist (1983).

7.04.3.3.1 Diabetes mellitus

The prevalence of diabetes for Caucasians aged over 65 in the USA is 7% for men and 9% for women. For the black population aged over 65, it is 12% for men and 15% for women (Zemel, 1988). Diabetes is an important cause of sexual dysfunction. Orgasmic impairments are experienced by 18%–35% of women. Impotence, retrograde ejaculation, premature ejaculation, and oligospermia are reported for men. At 65 years of age, up to 75% of diabetic men are impotent (Mooradian, 1991; Newman & Bertelson, 1986; Zemel, 1988).

7.04.3.3.2 Cardiovascular disease

Prevalence of this disease increases with age, and the disease causes over 50% of deaths in individuals aged over 64 (Wise, 1989). Both organic and psychological factors affect the sexuality of individuals suffering from cardiovascular disease. Orgasmic difficulties in women as well as erectile dysfunction and premature ejaculation in men are reported (Wise, Epstein, & Ross, 1992). Following coronary bypass surgery, the sexual desire of women appears to decline, while an increase in performance anxiety is common in men. Survivors of myocardial infarction often report anxiety and depression. Fear of sudden death during intercourse often leads to impotence. Patients are assured that they can have intercourse without any risk when they can climb two flights of stairs or can vigorously walk around a block without chest discomfort (Mooradian, 1991; Relf, 1991; Wise, 1989). This rule of thumb ignores interindividual differences in patients and, additionally, poses a psychological dilemma. Patients are allowed to resume sex but they have to watch cautiously for any signs of recurring angina. This anxious self-observation contradicts the "letting go" which is part of successful sexual experiences (Thienhaus, 1988).

7.04.3.3.3 Cancer

This disease continues to be the most dreaded diagnosis, which often leads to depression and anxiety. For most patients their initial question concerns survival. Cancer and its treatment has an intense influence on individual identity and self-esteem, and it can have negative effects on desire, arousability, and orgasm in females and males (Gendel, 1986; Kaiser, 1992; Schover, 1988a, 1988b; Schover, Evans, & Von Eschenbach, 1987; Schover, Schain, & Montague, 1989; Shell & Smith, 1994).

In women, breast and gynecological cancer and its treatment can have tremendously deleterious effects on self-image and sexual functioning. One out of nine American and European women experience breast cancer and the incidence is increasing (Kaplan, 1992). Schover et al. (1995) compared psychosocial adjustment, body image, and sexual function for 72 women who had experienced partial mastectomy and 146 women who had undergone immediate breast reconstruction after partial mastectomy. Contrary to expectations, the two groups did not differ in psychosocial adjustment to the illness, with fewer than 20% of subjects reporting poor adjustment. Women who had been treated with chemotherapy had more sexual dysfunction, poorer body image, and more psychological distress. Margolis, Goodman, and Rubin (1990) compared 22 patients who had experienced radical mastectomy with 32 women who had undergone lumpectomy combined with radiation therapy. Patients who had experienced mastectomy felt less attractive, less desirable, and experienced less sexual enjoyment than prior to treatment. Patients who had undergone radiation therapy reported no changes in these domains. Kaplan (1992) stated that all current treatments for breast cancer can have negative effects on female sexuality but that these side-effects are widely ignored by clinicians and scientists.

In men, the effects of prostate cancer on sexual functioning vary with treatment. Radical prostatectomy results in impotence in up to 85% of cases, but only 5% of patients reported impotence after transurethral resection; 80% of these patients stated, however, retrograde ejaculation which can reduce enjoyment (Mooradian, 1991; Wise et al., 1992). Penile cancer is a rare malignancy. Opjordsmoen, Waehre, Aass, and Fossa (1994) reported Norwegian data on 30 men. Their results indicate that radiotherapy preserves sexuality better than surgery or laser treatment. Partial or total penectomy severely reduces sexual interest and ability of performance.

Colon cancer often reduces sexual functioning because of psychological problems. Surgery may lead to an ostomy, and fear of stool leakage and odor may inhibit sexual responses (Kinn & Öhmann, 1986; Mooradian, 1991; Wise et al., 1992).

7.04.3.3.4 Renal failure

Many patients with decreased renal functioning report sexual difficulties. This disease is associated with various hormonal changes which may influence sexual potency (Mooradian, 1991; Wise et al., 1992).

7.04.3.3.5 Dementia

The prevalence of dementia is about 5% in individuals aged over 65, and 20% in persons over 85 (Helmchen et al., 1996; Henderson, 1986). Cognitive and personality changes of patients lead to considerable conflict, burden, and grief in relationships. Patients with Alzheimer's or multi-infarct dementia, however, may have an increase in libido, very often accompanied by inappropriate sexual behavior like exposure, public masturbation, or sexual harassment of caregivers (Mooradian, 1991). Litz, Zeiss, and Davies (1990) described psychotherapy with a man who experienced erectile dysfunction because of dramatic changes in his wife's sexual behavior due to Alzheimer's disease. Fedoroff, Peyser, Franz, and Folstein (1994) reported high frequency of sexual disorders in patients with Huntington's disease.

7.04.3.3.6 Depression

Next to dementia, depression is the second important psychiatric disease in the elderly (Helmchen et al., 1996; Henderson, 1986). Loss of libido is a common symptom of depression. Depression can be secondary to sexual dysfunction especially in men. These patients recover from depressive symptoms when sexual potency is improved. Unfortunately, mental health professionals often ignore elderly sexuality (Liptzin, 1984).

7.04.3.3.7 Use of medication

Treatment of chronic diseases almost always requires medication which may have considerable side effects on sexuality. Of the prescribed drugs, 31% are consumed by only 11.7% of the population, (i.e., elderly patients aged over 65) (Mooradian, 1991). Antihypertensive agents, major tranquilizers, minor tranquilizers, antidepressants, and miscellaneous other drugs may cause sexual dysfunction. Antihypertensive agents are probably responsible for the majority of dysfunction. They can lead to impotence, anorgasmia, and ejaculatory disturbances (Segraves & Segraves, 1992).

7.04.3.3.8 Institutionalization

Nursing home residents are often chronically ill and, therefore, dependent on caregivers (Baltes, 1996). Opportunities to express sexual feelings are often restricted because of three factors: disease-related sexual dysfunction, disapproval of sexuality by staff members, and lack of privacy (Hodson & Skeen, 1994; McCartney, Izeman, Rogers, & Cohen, 1987;Mulligan & Modigh, 1991; White, 1982). Nevertheless, institutionalized elderly people do have sexual needs and engage in sexual behaviors (Bretschneider & McCoy, 1988; White, 1982). This fact has been increasingly accepted by nursing staff, and the linkage between knowledge and attitudes towards elderly sexuality in staff has been explored (Commons, Bohn, Godon, Hauser, & Gutheil, 1992; Hillman & Stricker, 1994).

Summarizing age-related changes in sexual functioning, it seems obvious that sexuality in the elderly is not the same as in younger adults. Shaping interests in and capacity for sexual performance of older people, biology does play a role as well as socialization, individual biography with its unique events and experiences, and societal expectations. On the one hand, data show that healthy elderly people can have a satisfying sex life. On the other hand, sexual dysfunction increases with age due to the increase of chronic diseases and its treatment.

7.04.4 SEXUAL DISORDERS AND TREATMENT

Sexual functioning is often classified around three sexual response phases: desire, arousal, and orgasm (American Psychiatric Association [APA], 1994; Schiavi & Segraves, 1995). Sexual desire and sexual arousal are closely connected and the distinction between them raises scientific difficulties. Desire refers to the intensity of sexual drive whereas sexual arousal includes a subjective sense of sexual excitement. Orgasm is defined as being the peak of sexual pleasure and the release of sexual tension. Women are capable of multiple orgasms which can be experienced at the clitoral or the vaginal site. Some women experience them both, sometimes in a blended form, which are reported to be the most intense (McConaghy, 1993).

The following refers to the *Diagnostical and statistical manual of mental disorders* (4th ed.) (*DSM-IV,* APA,1994) classification. It will focus on sexual dysfunction and its treatment. The second and third group of sexual disorders, namely the paraphilias and the gender identity disorders, are not discussed here. A key diagnostic issue is the distinction between sexual disorders as the primary diagnosis versus loss of sexual functioning due to other medical or psychiatric conditions. The *DSM-IV* stresses this point by defining exclusion criteria for sexual desire disorders, sexual arousal disorders, and orgasm disorders as "the sexual dysfunction is not better accounted for by another Axis 1 disorder (except another sexual dysfunction) and is not due exclusively to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition" (p. 498). Other Axis 1 disorders include major depressive disorder and post-traumatic stress disorder. Sexual dysfunction in the elderly patient is often a secondary diagnosis, caused by chronic illness (Gupta, 1990; Kaiser, 1991; Leiblum & Segraves, 1989; Renshaw, 1984; Weiss & Mellinger, 1990).

Treatment of sexual disorders has changed considerably since the pioneering reports of Masters and Johnson (1966) about their success rates after two weeks of treatment, which had led to tremendous optimism with regard to sex therapy. Unfortunately, reports of successful treatment procedures had often to be corrected because long-term evaluations of the techniques failed to reveal long-term positive outcomes (Dekker & Everaerd, 1983; Fichten, Libman, & Brender, 1986; Kilmann et al., 1986). Therefore, optimism has diminished and sexual difficulties are regarded as complex problems which are the consequence of biological, psychological, cultural, and interpersonal influences. Since the late 1980s, four trends have been identified (Leiblum & Rosen, 1989b).

(i) Increased attention towards biological and medical causes, especially in the diagnosis of erectile difficulties. Vascular, hormonal, and neurological procedures have been developed in order to detect organic factors (Davidson & Rosen, 1992; Melman, 1992; Schiavi, 1992; Segraves & Segraves, 1992; Tiefer & Melman, 1989). The increased age of patients asking for sex therapy has contributed to this trend (Leiblum & Rosen, 1989b).

(ii) Increased pharmacological interventions. Again, erectile difficulties are one focus of attention. Antidepressant and antianxiety drugs are prescribed even for men with psychogenic erectile failures, which was unthinkable in the past. Kaplan and colleagues suggest pharmacotherapy in the treatment of sexual phobias and sexual aversion in addition to her psychodynamically and behavioral-oriented sex therapy (Kaplan, Fyer, & Novick, 1982; Leiblum & Rosen, 1989b; Othmer & Othmer, 1987). This trend is in line with the medical disease model and societal expectations that a sick body is like a machine and should be made to function again as quickly as possible.

(iii) Concentration on desire disorders. On the one hand, clinicians report the growing number of couples presenting desire discrepancies, with usually one partner reporting low desire (Leiblum & Rosen, 1988). On the other hand, there are case reports about sexual addicts or hyperactive sexual interest (Goodman, 1993).

(iv) A therapeutic shift from behavioral to interpersonal system concepts and psychodynamic object-relations theories. Short-term behavioral sex therapies, although successful in some cases, failed with many individuals and with complex problems (Bagarozzi, 1987; Kaplan, 1974, 1977; Leiblum & Rosen, 1992). Intrapsychic difficulties in attachment, dependency, and commitment as well as interpersonal systemic issues have become the focus of attention (Bagarozzi, 1987; Brown & Field, 1988; Leiblum & Rosen, 1992; Levay, 1983; McCarthy, 1984; Talmadge & Talmadge, 1986).

7.04.4.1 Sexual Desire Disorders

These disorders are hypoactive sexual desire disorder (HSDD) and sexual aversion disorder. HSDD is defined as:

> persistently or recurrently deficient (or absent) sexual fantasies and desire for sexual activity. The judgment of deficiency or absence is made by the clinician, taking into account factors that affect sexual functioning, such as age, sex, and the context of the person's life. (APA, 1994, p. 498)

This definition has been frequently criticized because it does not give clear-cut criteria such as length of time, and is therefore highly subjective (LoPiccolo, 1985). Nevertheless, clinicians agree that low or absent desire is one of the most prevalent psychosexual problems seen by them (Leiblum & Rosen, 1988; Rosen & Leiblum, 1989). Desire disorders are believed to be highly refractory to treatment because they are supposed to be a symptom of severe intrapsychic conflicts. Radin (1989) provided a theoretical and clinical understanding of this disorder proposing that preoedipal factors and psychological defense mechanisms that originated during the pregenital years play a significant role in the etiology. Schreiner-Engel and Schiavi (1986) tried to prove the assumption of severe underlying psychopathology. They compared 46 couples with one partner who had inhibited sexual desire with 36 controls. Results showed that individuals with inhibited desire had a history of major and/or intermittent depression twice as high as controls. Furthermore, depressive disorder coincided or preceded sexual dysfunction.

Donahey and Carroll (1993) raised the question whether there is in fact an increase in hypoactive sexual desire, or whether individuals or couples define this as a problem because sexual functioning has become very important in Western cultures. They reported that biological, psychological, and interpersonal factors have been discussed in the etiology of hypoactive sexual desire and that these factors are assumed to affect men and women equally. Donahey and Carroll (1993) hypothesized that hypoactive sexual desire develops and manifests itself differently for men and women. They investigated 47 males and 22 females and found that women reported more stress, and that they were less satisfied with their marriages. The authors suggested that treatment for women should focus more on psychological symptomatology and relationship issues. LoPiccolo (1985) noted that low sexual desire is inconsistent with the cultural expectation and fantasy of male sexuality. Therefore, it is an interesting phenomenon but empirical data are lacking.

Kaplan & Owett (1993) contributed an important physiological reason for inhibited desire in females. They showed that a loss of androgens is associated with a marked decrease in sexual desire and libido. This observation should be further investigated, because the Kaplan and Owett data stem from cancer patients who underwent chemotherapy and, thus, other explanations for decreased interest in sex are also plausible.

The differentiation between sex therapy and psychotherapy has become increasingly difficult. One reason for this change is the growing interest in sexual desire disorders. Many authors have argued that chronic desire disorders can only be treated within individual psychotherapy, in particular psychodynamic approaches, psychoanalysis, and object-relations therapy (Kaplan, 1977; Levay, 1983; Levine, 1988; Radin, 1989; Scharff; 1988; Talmadge & Talmadge, 1986).

Other authors have argued for cognitive-behavioral or systemic-interactional approaches. The necessity of exploring sexual scripts in order to understand sexual fantasies, unreal ideals, and false beliefs has been stressed (Lazarus, 1988; LoPiccolo & Stock, 1986; McCarthy, 1984; Rosen & Leiblum, 1988; 1989). Furthermore, the couple's relationship has to be examined carefully. For example, inhibited sexual desire in one individual can be a very effective means for regulating power distribution (Bagarozzi, 1987).

Some authors have suggested pharmacotherapy for treatment of low desire. Despite some successful reports, results have not been convincing (Leiblum & Rosen, 1989; Segraves, 1988).

Sexual aversion disorder is defined as "persistent or recurrent extreme aversion to, and avoidance of, all (or almost all) genital sexual contact with a sexual partner" (APA, 1994, p. 500). This syndrome occurs in both females and males. Crenshaw (1985) differentiated between primary and secondary aversion. Primary aversion is characterized by a negative response to any sexual interactions from the earliest memories to the present and is often combined with other dysfunction. A psychosexual trauma like incest or child molestation is frequently found. Secondary aversion is acquired, which means that sexuality was found pleasurable in the past. In the beginning of the disorder individuals may function well sexually when they get involved in sexual activities. The differentiation between the two desire disorders is often difficult. There are no special treatment suggestions.

7.04.4.2 Female Disorders

LaFerla (1984) listed a number of factors contributing to female sexual dysfunction in desire and orgasmic response. He differentiated psychosocial and organic factors. Psychosocial factors are relationship issues, negative past experiences, and depression as well as drug and alcohol abuse. Organic factors are chronic illness, pregnancy, pharmacological agents, and endocrine alterations.

7.04.4.2.1 Arousal disorder

For females, arousal disorder means a "persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement" (APA, 1994, p. 502). The excitement phase in elderly women is much slower than in younger ones. Whereas in young women lubrication occurs after 10–15 seconds, it requires at least five minutes in the postmenopausal women (Gupta, 1990). However, this change is normal and cannot be considered a disorder. Some women produce insufficient vaginal lubrication altogether, and they may need artificial lubricants.

7.04.4.2.2 Orgasmic disorder

The female orgasmic disorder is defined as a:

> persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase. Women exhibit wide variability in the type or intensity of stimulation that triggers orgasm. The diagnosis of female orgasmic disorder should be based on the clinician's judgment that the woman's orgasmic capacity is less than would be reasonable for her age, sexual experience, and the adequacy of sexual stimulation she receives. (APA, 1994, p. 506).

Orgasmic disorder is still one of the most frequent sexual dysfunctions in women. It is divided into primary and secondary anorgasmia. Primary anorgasmia refers to women who have never experienced an orgasm, secondary anorgasmia refers to women who sometimes or in specific situations (e.g., masturbation) react orgasmically. Empirical data from cross-sectional studies suggest that the rate of women who never or rarely react with orgasm decreases from 50% in young adulthood to 21% at the age of 40 (McConaghy, 1993), remains fairly stable with 21% between the ages of 40 and 59 (Laumann et al., 1994), and increases to 28% over the age of 70 (Bergström-Walan & Neilsen, 1990; Brecher, 1984). Nevertheless, these data are difficult to evaluate. Concerns about women's orgasm are a rather new phenomenon. Women can have an orgasm in the same amount of time as men, and they can achieve multiple orgasms. Personal history, relationship difficulties, lack of education, and lack of knowledge about sexuality may be reasons for the inhibition of the orgasmic response. Very little is known about factors that contribute to orgasmic capacity. The neurophysiological basis of human orgasm is underexplored (Heiman & Grafton-Becker, 1989).

Treatment approaches of this disorder depend on the theoretical orientation of the therapist. Three major approaches are psychoanalytic, cognitive-behavioral, and systemic theory. Psychoanalytic psychotherapy does not focus on symptom removal but on working through underlying conflicts that lead to the symptom. Once these conflicts are understood and worked through, symptoms disappear. Kaplan (1974, 1977) combined a psychodynamic approach with behavioral sex therapy elements.

Cognitive-behavioral therapy depends on learning theory and tries to promote cognitive as well as behavioral changes. Behavioral exercises, like directed masturbation, partner stimulation, and Kegel exercises, are frequently used. Whereas directed masturbation seems to be successful in treatment of primary anorgasmia, its long-term effectiveness in treating secondary anorgasmia is questionable (Fichten, Libman, & Brender, 1986; Kilmann et al., 1986; Kuriansky, Sharpe, & O'Connor, 1982; Nairne & Hemsley, 1983; Wakefield, 1987).

Systemic therapists concentrate on the couple as a system and do not focus on the individual woman with anorgasmia. Her dysfunction is regarded as a problem of the system. Thus, therapists focus on interactional patterns. Heimann and Grafton-Becker (1989) suggested an integrated theory and practice that combines the theoretical and practical elements of psychoanalytic, cognitive-behavioral, and systemic theories.

7.04.4.2.3 Sexual pain disorders

Dyspareunia and vaginismus are sexual pain disorders. Dyspareunia is a "recurrent or persistent genital pain associated with sexual intercourse in either a male or a female" (APA, 1994, p. 513). This disorder can have organic and/or psychological causes. Careful assessment and diagnosis is very important (Sandberg & Quevillon, 1987). Lazarus (1989) described three psychological factors, namely traumatic (e.g., rape), developmental (e.g., religious taboos) and relational (e.g., resentment, insufficient sexual stimulation through partner). Unsatisfactory relationships are the major reason for this dysfunction. After a careful multimodal assessment, treatment depends on the identified cause and may consist of different methods (e.g., relationship enhancement, social skills training, imagery techniques, systematic desensitization, and sensate focus).

Vaginismus is defined as a "recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that interferes with sexual intercourse" (APA, 1994, p. 515). Women with vaginismus may function sexually without difficulties except their inability to have intercourse. Different psychological theories agree that anxiety is the core of these spastic contractions. Treatment very often consists of the gradual insertion of objects in the vagina. Dilators with increasing size are frequently used. Examples of treatment with different outcomes are discussed by Leiblum, Pervin, and Campell (1989).

7.04.4.3 Male Disorders

7.04.4.3.1 Arousal disorder

For males, arousal disorder is defined as erectile disorder: "Persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate erection" (APA, 1994, p. 504). Erectile difficulties increase with age and they are the major sexual problem of elderly males (Kaiser, 1991; Levine, 1992; Nelson, 1987; Rosen & Leiblum, 1992a, 1992b; Segraves & Segraves, 1992; Weiss & Mellinger, 1990).

For many years psychological factors have been perceived as major causes of erectile difficulties, and organic causes have been widely overlooked. Recent work has focused on differential diagnosis of physiological and psychological factors (Kinder & Curtiss, 1988; LoPiccolo, 1985). Levine (1992) suggested four categories for classification: psychogenic, organic, mixed, and idiopathic (when the professional cannot identify the cause with certainty). Disease or drug-related erectile failures are common in elderly men but psychogenic factors may work in addition.

Intensive research efforts have focused on the determinants of erectile dysfunction. In addition, numerous treatment approaches have been tried (Rosen & Leiblum, 1992). Modern psychotherapeutic treatment concentrates on the systemic function of erectile difficulties (Althof, 1989; Levine, 1992; Leiblum & Rosen, 1992; LoPiccolo, 1992; Speckens et al., 1995).

Surgical treatment has become very important in recent years. There is surgical correction of reversible dysfunction and, in cases of nonreversibility, penile prosthesis can be implanted. Implant devices have, however, considerable risks and disadvantages, and careful consideration has to precede surgery (LoPiccolo & Stock, 1986; Melman & Tiefer, 1992). Injection therapy and vacuum devices are also widely used (Althof & Turner, 1992; Kaplan, 1990).

7.04.4.3.2 Orgasmic disorders

In males, there are two orgasm disorders, namely the male orgasmic disorder and premature ejaculation. Male orgasmic disorder is defined as a "persistent or recurrent delay in, or absence of, orgasm following a normal sexual excitement phase during sexual activity that the clinician, taking into account the person's age, judges to be adequate in focus, intensity, and duration" (APA, 1994, p. 509). This disorder is not often seen in a clinical context. Apfelbaum (1989) proposed that the retarded ejaculator is more responsive to his own stimulation and experiences hostility towards his partner. The patient has to become aware of his distance and anger before he can make any progress.

Premature ejaculation is defined as a "persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it" (APA, 1994, p. 511). This disorder is more common in younger men and its treatment seems to be very effective. Information about different treatment techniques are given by LoPiccolo (1985), LoPiccolo and Stock (1986), and McCarthy (1989).

7.04.4.4 Special Issues in Treatment with Elderly Patients

Basically, there are no differences between sexual difficulties and dysfunction between younger and older adults. Nevertheless, there are some issues which should be considered. First, biological changes with age and health-related factors have to be explored thoroughly. Second, cohort experiences and values have to be considered. Third, life events and circumstances have to be evaluated (Leiblum & Segraves, 1989; LoPiccolo, 1991).

Physiological and health-related changes have been previously described in this chapter. Clinical observations about the behavior of hundreds of elderly men, women, and couples who have sought help for sexual difficulties revealed adaptation processes to the major physiological changes. Kaplan (1990) summarized that couples who have a good and intimate relationship, who care for each other and each other's pleasure, and who are sexually open and free of severe conflicts, can adapt to these changes very successfully. She described the following coping mechanisms that may help to maintain sexual functioning:

(i) *Diminished sexual desire*. This problem may occur in either one or both partners and can be overcome with the help of fantasies or erotica. Testosterone replacement is helpful in some cases. Treatment of possible depression or substance abuse might be necessary.

(ii) *Higher penile threshold for mental and physical stimulation/delayed lubrication*. These problems can be solved with partner-provided, extended physical stimulation. Erotica or fantasy and more rapid love making are helpful. Morning sex is recommended because elderly men function better in the morning due to higher testosterone levels.

(iii) *Vaginal dryness and atrophy; dyspareunia*. Use of lubricants prior to coitus and/or estrogen replacement are beneficial. Intercourse on a regular basis and dilators may be useful.

(iv) *Softer penile erections*. Coital positions which facilitate intromission (e.g., stuffing) are recommended. Stimulation, enjoyment, and orgasms by manual or oral practices should be emphasized.

(v) *Lengthened male refractory period*. This causes less frequent intercourse. Quality vs. quantity of experience should be emphasized.

(vi) *Physical mobility and pain*. Analgesics taken before sexual activity or a hot bath to reduce stiffness may help. A side-by-side-position is often more comfortable.

Counseling or treatment should be done cautiously. Very often, information about age-related changes and "permission giving" of new experiences (e.g., more manual or oral stimulation, fantasies, new positions) are helpful. Keeping in mind cohort differences, the therapist should carefully evaluate the patient's value system and possible shame reactions before any suggestions are made. Middle-class values of younger adults are easily imposed and might substantially harm the elderly patient. For example, masturbation, oral sex, or the use of a vibrator may be common practices for sex therapists but not necessarily for a couple born in the countryside in the 1920s.

In some cases, sexual dysfunction of elderly patients has a severe underlying conflict. For example, meeting the psychosocial crises of ego integrity or ego despair may result in sexual dysfunction (Fagan, Meyer, & Schmidt, 1986). In these cases individual psychotherapy should be considered. Contrary to common beliefs and stereotypes of many psychotherapists of all theoretical backgrounds, psychotherapy can be very successful with elderly patients (Radebold, 1992; Smyer, Zarit, & Qualls, 1990). It is important, however, that psychotherapists of elderly people have some gerontological and historical knowledge, and that they are aware of special countertransference issues (Apfel, Fox, Isberg, & Levine, 1984; Radebold, 1992).

Finally, it has to be recognized that sexual behavior is not easily modifiable. Sexual anxiety, which is believed to be the core of most sexual dysfunction (Patterson & O'Gorman, 1989), has "an important adaptive feature of human sexual behavior" (Cole, 1985, p. 337). Cole presented a critical review about sex therapy and its outcome research. He concluded that sex therapy has intrinsic limitations which have to be accepted. Vandereycken (1987) argued in addition that sexual lust has turned from a taboo into a "must." The establishment of new behavioral demands should certainly not be the result of gerontological research and psychotherapy with elderly people. Therefore, careful and critical reflection of scientific data and therapeutic aims is crucial.

7.04.5 CONCLUSION

This chapter has examined literature on sexuality and aging. In spite of the growing body of research on old age and aging, there is a considerable lack of sound studies in the context of sexuality and aging, particularly with respect to elderly women. Epidemiological data have been presented and their methodological and theoretical problems described. Age-related physiological changes in women and men were examined. It is important to differentiate between normal age-related changes and health-related problems. Chronic disease increases with age, but deleterious effects on sexual enjoyment are due to disease, and not to aging *per se*. Sexual disorders of desire, arousal, and orgasm as well as treatment approaches have been described. Finally, sexuality of the elderly individual should be embedded in a life-span developmental perspective. The important role that the individual biography plays in the aging process is an accepted fact in modern gerontology. Further research should pay more attention to intra-individual development. Many research results (e.g., differences in sexual activities between men and women) may be due to cohort effects and not to biological factors.

7.05.1 INTRODUCTION

Issues about death surround everyone's daily lives, yet most people neglect to use these opportunities to improve their understanding of grief. A plane carrying hundreds of passengers crashes in the Florida swamps and Americans watch with interest on television and read in newspapers and magazines about the loss of lives, grieving families, heroic workers trying to retrieve bodies, and the need for improved safety standards in the airline industry. Another assisted suicide is described in the media but very few people ever discuss the grief of the family members. The evening news regularly reports on the victims of gang-related murders that occurred the previous night. Local newspaper obituaries include another person who has died from AIDS. Each of these four examples contain in-depth stories of human emotion and relationships in the lives of the victims and survivors, yet most passive onlookers fail to realize that they will share many of the same emotional and social experiences that these distant "people in the news" have had to encounter. While most people never experience horrendous or public deaths nearly everyone will have several personal bereavement experiences during their lives. Individuals could benefit from learning more about death and grief by more closely examining some of these news events and people and assessing their own personal feelings and reactions. Instead, most people only learn about death, grief, loss, and bereavement when they have no other choice because it is now their own personal experience.

In order better to describe the complexities of the bereavement process and how we might best assist those who have the greatest difficulty, this chapter will summarize and highlight some of the most basic and essential knowledge available. The chapter begins with a review and discussion of the many common but highly diverse bereavement experiences that occur throughout the life course. Although the primary focus is on bereavement in later life it is necessary to place these losses in the context of the entire life course because earlier experiences continue to impact coping strategies used in late life. Bereavement is also examined in a multidimensional context because it can affect nearly every aspect of a person's life. Knowledge about grief and bereavement comes from a variety of experts and sometimes the information is contradictory or inconsistent, so it is important to understand the advantages and limitations from these diverse sources. This section is presented along with a discussion of the benefits from integrating theory, research, and clinical practice to achieve a better understanding of the bereavement process. Reviewed next are the most common features of the long-term process and predictors of who is most likely to have the greatest difficulty. The chapter ends with a review of the most promising ways to intervene to assist those in greatest need, and some additional comments about the need to be creative and collaborate with others from a variety of different disciplines.

Many people use the terms bereavement, grief, and mourning as though they were interchangeable or have the same meaning. This is not the case. All three of these terms are highly interrelated but it is important to note that each has a unique meaning.

Bereavement is the broadest or most general of the three terms because it refers to both the situation and the long-term process of adjusting to the death of someone to whom a person feels close (Lund, 1993). The term also has been used in reference to losses other than death, such as the loss of a home or personal belongings because of a fire or a natural disaster. It is more common, however, to use the term bereavement in situations following the death of a friend or relative, or even an animal companion. Grief and mourning are more specific in their meaning because they refer to different aspects of the overall bereavement process. Grief refers specifically to the affective or emotional responses that people often experience during the early phases of the bereavement process. These feelings frequently include disbelief, confusion, shock, numbness, sadness, and sometimes anger and guilt. Feeling abandoned, lonely, or depressed, and being preoccupied with thoughts of the deceased person and the events surrounding the death are often components of grief (Parkes, 1987).

It is common for bereaved persons to feel a wide range of emotions that come and go quickly and then reappear many months or even years later. These grief-related feelings do not come as a set package to all bereaved persons. Each person experiences a relatively unique array of emotions with varying levels of intensity and duration. Culture plays a major role in shaping how people experience and express bereavement because it provides the beliefs, values, and norms that guide behavior (Lund, 1989b). Most professionals use the term mourning to refer to the commonly accepted or culturally patterned ways people behave and express themselves during the adjustment process (Lund, 1993). Mourning refers to such behaviors as crying; missing work; altering daily routines; attending funerals, cremations, and burials; following standards for dress and appearance; and participating in other rituals that are influenced by the surrounding culture. Each culture has traditions to determine the most appropriate ways to behave (Chigier, 1988; Stroebe & Stroebe, 1987). Some cultures avoid open displays of sadness yet others expect the bereaved to be vocal and demonstrative (Irish, Lundquist, & Nelsen, 1993). Each of these three related terms will be further clarified later in this chapter along with discussion of the many commonalities and diverse ways that people experience bereavement.

7.05.2 LIFELONG BEREAVEMENT EXPERIENCES

Throughout the life course nearly everyone experiences many kinds of losses that require them to make adjustments. Infants become temporarily separated from parents and siblings when they leave the familiar surroundings of the home to attend day care and school. With increasing numbers of dual-career couples, children are leaving their homes at much younger ages to spend much of their weekday time away from both parents. Children also lose toys, clothes, pets, and valued belongings. With increased geographic mobility it is becoming common for children to move several times from one neighborhood to another, changing friends and familiar surroundings with each move. Young adults have lost relationships with teachers, clubs, organizations, and peers, as they advance from elementary grades, through high school and college. In later life adults continue to lose more friendships and relationships because of relocations, deaths, and retirement. With divorce rates near 50% in the USA (Hess, Markson, & Stein, 1996), millions are experiencing the loss of marital relationships, parents, and family life. Due to physiological changes associated with aging, people often lose hair, hearing, sight, muscle tone, independence, and mobility. In short, people who are fortunate to live long lives will experience many significant losses. Each loss has the potential of disrupting patterns of behavior, initiating grief-related feelings and requiring adjustments, but also adding to the course of human development.

Older adults have many opportunities to develop their coping skills or become overwhelmed by life's cumulative losses. It is much easier to understand how people cope with their current bereavement situations if one recognizes how they have managed their previous losses. For example, in the case of older bereaved spouses, effective interventions need to take into account how they experienced relocation, physical, and relationship losses earlier in their life (Lund, 1989a). If they relied on task-oriented strategies in handling these previous situations then a similar approach might be effective again. At the same time we need to appreciate the uniqueness of each loss or bereavement experience and not assume that the loss of personal belongings is the same as a divorce or death of a parent. While sadness might be a grief response common to both relocation and the death of a parent, it is unlikely that anger or guilt would be equally present in both situations (Farnsworth, Pett, & Lund, 1989).

The field of gerontology has been redefined since the late 1970s to give greater recognition to aging as a lifelong process (Hooyman & Kiyak, 1996). Rather than being exclusively focused on older adults, it recognizes that aging occurs throughout the life course but the primary focus still remains on later life. The most common death-related losses of interest to gerontologists are the deaths of parents, spouses, siblings, and friends. Much of the information in this chapter is based on spousal bereavement in later life because more gerontological research has focused on this particular loss. Children's death-related bereavement experiences are most likely to result from the death of a neighbor, parent, older relative, or school classmate. Some experts have described the death of a parent as the loss of our past, the death of a spouse or sibling as the loss of the present, and the death of a child as a loss of part of our future (Leming & Dickinson, 1990; Schiff 1977; Staudacher, 1987). Again, early and consistent experiences with death-related losses can shape subsequent attitudes and ways of coping well into later life (Lund, 1993). For example, the young boy who is told to be strong and not to cry after his father's death might easily grow up to be the unexpressive and isolated widower in later life.

Although statistics cannot capture the full essence of the bereavement process they are very helpful in documenting the commonality and expectedness of the experience. Each year approximately eight million Americans experience the death of an immediate family member. Even though suicides are underreported in the USA roughly 27 000 are reported each year. Over 400 000 of the deaths are children and youths under the age of 25. Also, each year there are at least 800 000 new widows and widowers (Osterweis, Solomon, & Green, 1984).

The death of a spouse is an increasingly common experience among aging adults, particularly women. The 1990 Census revealed that only 1% of the population between ages 18 and 54 were widowed, but 34% of those 65 and over and 67% of those 85 and over were widowed. A gender difference becomes increasingly apparent in the later years of life. After age 65, nearly 49% of the women but only 14% of men were widowed. After age 85, 80% of women and 43% of men were widowed (US Bureau of the Census, 1991). These high percentages actually underestimate the number of persons who experience the death of a spouse because they do not include those who remarried. In short, death-related bereavement is a common and expected experience for older adults.

7.05.3 BEREAVEMENT IN A MULTIDIMENSIONAL CONTEXT

One of the major reasons why bereavement has become such an important topic to clinicians, researchers, health professionals, clergy, and educators is the growing recognition that the adjustment process can impact virtually every aspect of a person's life (Lund, 1989b; Shuchter, 1986; Shuchter & Zisook, 1993). This pervasive and multidimensional nature of bereavement means that the coping process can affect emotions, spirituality, identity, social interactions and relationships, sexuality and intimacy, work productivity, financial stability, health, and even death. Clinicians and others who are interested in providing assistance to the bereaved need to recognize the broad range of possible effects and determine the extent to which bereavement is the cause of the difficulty. For example, patterns of interaction in family life can be radically altered when someone dies. Family meals, and other daily rituals related to getting ready for work, school, or church are affected by the absence of the deceased family member. Worden (1991) presents this difficulty as one of four tasks of mourning. He refers to this as the need to adjust to an environment in which the deceased is missing. These tasks of mourning are discussed in more detail later in this chapter. In the case of spousal bereavement survivors often change their self-concept to an "uncoupled identity" because they now carry out their daily life alone rather than as part of a couple (Lund, Caserta, Dimond, & Gray, 1986). Our society places great importance on adults doing many activities as couples rather than doing them alone. Imagine the difficulty of a bereaved spouse going alone to a movie or restaurant after many years of always doing these things with their husband or wife. Bereaved persons may also lose their appetite and motivation to remain physically active so nutrition, exercise, and physical well-being can be essential parts of the coping process (Lund, 1989a).

The multidimensional nature of bereavement is evident in the topics that professionals from different disciplines choose for special attention. Sociologists often examine bereavement's impact on family life, interactions, life satisfaction, and the role of culture and socioeconomic characteristics in shaping these bereavement outcomes. Finding differences among men and women, rich and poor, and diverse ethnic groups are common concerns for sociologists. Psychologists frequently examine the emotions of grief, depression, morale, and identity, and how previous relationships and the personality of the bereaved influence their coping strategies. Social workers are likely to assess family functioning and the need for, and effectiveness of, specific community services. Nurses and other health professionals are often concerned about the mental and physical well-being of bereaved persons. Economists are usually interested in the financial stability of bereaved persons and their families. Because many women in the USA do not have the same level of retirement and other financial benefits as men, they are much more likely to suffer economically during widowhood (Caserta, Lund, & Dimond, 1989). Each discipline and professional group adds a unique focus to examining bereavement experiences, and collectively, we better understand the many ways that bereavement can affect our lives. Clinicians interested in further reading about the many dimensions of grief and bereavement should read Shuchter (1986), Worden (1991), and Stroebe, Stroebe, and Hansson (1993b). These references also include recommendations based on international research studies.

The multidimensional nature of bereavement cannot be understood without an awareness that bereavement takes place within a broad context that varies from person to person. Although there are many common reactions and feelings that most people experience during the course of bereavement, there also are many unique experiences that may not be widely shared. For example, some bereaved persons feel intense guilt and anger while others feel a general sense of relief because the deceased is no longer suffering pain and discomfort. Some are overwhelmed with sadness and immobilized by depression while others confront the loss as a challenge and opportunity for growth. In order to understand why one person manages very well and another never seems to adjust to the loss, it is necessary to examine the multidimensional nature of the context in which bereavement occurs (Cleiren, 1993; Lund, 1989b). Previous life experiences, personality traits, social support received from others, circumstances surrounding the death, and a person's competency in managing the many tasks of daily living are some of the many factors that comprise the context of bereavement. Health professionals and clinicians who work with bereaved persons are better able to provide assistance when they know more about the specific aspects of each individual's bereavement context. What helps one person may not be of much value to another.

7.05.4 EXPERTS ON BEREAVEMENT

For thousands of years the subject of death has received considerable thought and discussion but much less attention has been devoted to the subject of how death affects those who are left to grieve (Stephenson, 1985). Since the Second World War, however, we have seen a steady increase in interest and writing about bereavement. Various kinds of experts have emerged during this time, each relying on different experiences, training, and sources of knowledge. Academic disciplines, especially psychology, sociology, social work, nursing, and other behavioral and health professions have contributed attention and knowledge to the subject through the development of theory and research (Stroebe et al., 1993b). Clinicians who work directly with the bereaved have added their knowledge about ways to help those who are having the greatest difficulty (Rando, 1993; Worden, 1991). Religious leaders and clergy from various denominations have shared their experiences regarding spiritual aspects of the bereavement process (Grollman, 1977; Kushner, 1982). Local bookstores are now replete with numerous autobiographical reports written by bereaved persons who have had experiences that they want to share (Caine, 1974; Lewis, 1961). These five sources of expertise and knowledge—theory, research, clinical reports, religious views, and autobiographical accounts—each make unique contributions to our understanding of bereavement. These different sources of knowledge, however, have unique advantages and limitations that need to be recognized because they can lead to different and competing conclusions.

Some bereaved persons will automatically turn to their religious leaders or their religious beliefs for comfort and guidance. Most religions have a set of beliefs regarding the questions of ultimate meaning. What is the purpose of life? Does God or a supernatural being have a plan for each specific person? Is there special meaning in the death of the loved one? Because most religions offer answers to these and other questions, religiously oriented people can find predictability, structure, and meaning to help them during the upheaval of bereavement. Research has shown that religion and spirituality are only part of the bereavement context and that the long-term adjustment process involves much more than a religious code to follow (Faletti, Gibbs, Clark, Pruchno, & Berman, 1989; Gass, 1989a; Lund, Caserta, & Dimond, 1988). In fact, some bereaved persons report disappointment that their religious beliefs did not provide greater comfort and relief. Research has not confirmed that religious beliefs and practices are universally helpful to bereaved persons but we do know that many people turn to their spiritual views as a source of knowledge and assistance (Lund, 1989a).

Personal accounts written by bereaved persons are abundant because bereaved persons want to know how others have managed, if their experiences are unique or common, and how they can cope better with their loss. These autobiographical accounts can be useful because they offer detailed descriptions of feelings, problems, and solutions that worked for the authors. Some bereaved persons, for example, might find comfort in knowing that their feelings of anger and guilt were shared by the author and may benefit by following some of the suggestions in the book. Kushner's (1982) *When Bad Things Happen to Good People* has continued for many years to be on the best-sellers list because bereaved readers often find comfort in his expressions of anger, sadness, and even in some disappointment in his previous long-standing religious beliefs. Caution should be exercised, however, in fully relying on these autobiographical accounts because the authors' experiences may not be widely shared and their credentials are most likely in journalism rather than bereavement.

Therapists, counselors, psychologists, psychiatrists, and other clinicians have provided valuable information and insights about bereavement. Like autobiographical accounts, clinical reports often offer detailed personal descriptions of the bereavement process and suggestions for helping to alleviate some of the most difficult problems. These in-depth reports about individuals' bereavement experiences are not only interesting but they help to organize experiences of more people, identify serious but common adjustment difficulties, and inform other professionals and bereaved persons of specific intervention strategies and their potential benefits. Knowledge that comes from clinical practice, however, must be interpreted in a way that recognizes the uniqueness of the clients or patients. Those who receive counseling or professional clinical services are likely to differ in some important ways from those who never seek help (Caserta & Lund, 1992a). Bereaved persons who receive these services are more likely to be experiencing the greatest difficulty in adjusting, have less social support available to them, have financial resources adequate to pay for the services, and have a tendency to rely on others for help (Caserta & Lund, 1992a). Knowledge about bereavement based solely on information from those who sought help from clinicians does not include the experiences of the majority of bereaved persons (Lund, Dimond, & Juretich, 1985; Stroebe & Stroebe, 1987). It is equally important to know how people manage their grief on their own and to what extent they want and need help even though they do not seek professional assistance.

Theory and research have been much slower in adding to our knowledge about bereavement but their contributions have been essential. Freud (1957) was one of the earliest to theorize about bereavement. In the early 1900s Freud practiced and wrote extensively about psychoanalytic theory and applied it to understanding the feelings and thoughts that follow separation or loss of attachment. His work was followed by other theorists and eventually systematic research studies were completed. Lindemann (1944) also used a psychoanalytic framework to guide perhaps the first bereavement study in the 1940s. His study interviewed over 100 relatives of 13 people killed in a fire at the Coconut Grove night club in Boston. Research and theory related to bereavement has steadily increased since these early beginnings (Stroebe, Stroebe, & Hansson, 1993a). Numerous theories and research findings have emerged that both support and challenge what we initially believed to be true about bereavement. These early theories and more recent conceptual frameworks are discussed in greater detail later in this chapter.

Research has generated knowledge on a much broader range of bereaved persons. By collecting data from people who have not sought professional help, and including persons from varied cultures and social classes, we have learned much more about what is common and what is unique during bereavement (Caserta & Lund, 1992a). Systematic research studies, using well-developed and standardized scales, representative samples of bereaved persons, and nonbereaved control groups, have revealed findings that are inconsistent with and challenge some of the previous views based upon the other sources of knowledge (Stroebe & Stroebe, 1991; Wortman & Silver, 1989). These research findings are presented in more detail in Section 7.05.7. One of the most prominent research findings is that while bereavement is a highly stressful experience and some people report never getting over it, the majority of bereaved persons are very resilient, especially older bereaved spouses. Many bereaved persons find personal and social resources to meet their needs and manage their adjustment process. Research has also not been able to confirm that people go through specific stages as suggested by many clinicians and some theorists (Lund, Caserta, & Dimond, 1986; Shuchter & Zisook, 1993; Wortman, Silver, & Kessler, 1993). The process is much more varied and complex than the uniform and orderly course depicted in the stage theories (Bowlby, 1969). Research has revealed that not all people need to express in equal amounts their emotions outwardly to others in order to avoid a build-up of problems that will come out even worse later (Wortman & Silver, 1989). Many people who appear in control and able to manage their early grief tend to be doing very well years later (Wortman et al., 1993). Conversely, those who were doing poorly and were most expressive of their difficulties in the first several weeks were still having great difficulty two years later. These findings appear to be similar for adults of all ages (Lund, Dimond, et al., 1986; Wortman et al., 1993). In short, all five types of experts and their unique experiences and knowledge have added to a more comprehensive and useful understanding of bereavement.

7.05.5 THEORIES ABOUT BEREAVEMENT

The bereavement process is multidimensional and requires professionals from different disciplines to contribute their specific theories of human behavior to our understanding, explanation, and prediction of how people will experience this complicated process. Various conceptual frameworks have been applied to grief and bereavement, each providing a unique focus on specific parts of the bereavement context. These theories are particularly valuable if they predict adjustments and guide the development of interventions to help those in greatest need. The following sections briefly summarize some of the most prominent theories about grief and bereavement.

7.05.5.1 Psychoanalytic Theories

Most of the variations in psychoanalytic theory that have applied to bereavement emphasize the importance of recognizing the conscious and subconscious ties or attachments that the bereaved person formed with the deceased (Cleiren, 1993; Parkes, 1987; Stroebe et al., 1993a). According to this view the bereaved person must express rather than repress all of the feelings associated with the detachment or loss. Anger, guilt, fear, and love, when expressed by the bereaved, help lead to normal instead of abnormal grief. These theories also stress the importance of early childhood relationships and separations because these first experiences remain throughout life. When children have traumatic losses in early life they often form ambivalent relationships later, repress their anxieties, and have greater difficulty with grief and bereavement. Separation anxiety is seen as an instinctive reaction to loss but it is essential that the bereaved person withdraw from the deceased and form new attachments.

Freud (1957), Lindemann (1944), Bowlby (1969), Parkes (1987), and Marris (1958) are the most prominent contributors to the application of psychoanalytic theory to bereavement (Cleiren, 1993). While all theorists have their own unique interpretations they have generally agreed that grief is largely an intrapsychic process that each bereaved person must cognitively resolve in order to avoid delayed, distorted, or abnormal grief. Some of the abnormal reactions include social withdrawal, hypochondriacal symptoms, psychosomatic illnesses, and hyperactivity. Normal grief is thought to be marked by distress and impaired functioning but recovery is to be expected (Parkes, 1987). Bereaved persons usually experience a period of upset, protest, and anxiety because of the separation. They are likely to search for the deceased in familiar settings. Despair and depression can follow because the deceased person does not return. A reorganization phase occurs when grievers accept the reality of the loss, resolve the feelings of guilt and anger, restructure their lives and return to normal functioning (Parkes, 1987; Worden, 1991). These theories suggest that bereavement follows a relatively ordered progression of phases and that unresolved grief occurs when the sequence is disrupted or distorted.

7.05.5.2 Stress, Appraisal, and Coping Theories

Theories of stress, appraisal, and coping have been applied to bereavement because the death of a spouse, parent, child, or sibling is generally considered to be among the most stressful events that can ever happen. Stress exists when the demands on the individual exceed the resources readily available to meet the demands. The death of a loved one, particularly when the deceased played an important part in the daily life of the bereaved, creates stress in many ways for the survivor. Daily life is radically changed because the bereaved can no longer rely on the deceased for on-going companionship, conversation, security, guidance, comfort, love, sharing, and listening; and instrumental assistance such as financial support, transportation, and caregiving. Bereavement requires the survivor to change and adjust to an environment where the deceased is absent (Worden, 1991).

When bereavement occurs people must cognitively appraise their situation, usually consistent with their previously established patterns of dealing with stress. Cognitive appraisal means that people consciously assess their loss, try to make sense out of it, and determine the consequences that are likely to result from different courses of action. The degree of stress and subsequent adjustment difficulties is largely dependent on the bereaved person's appraisal of the situation and the coping strategies used.

The most common types of appraisal are pain, threat, challenge, and relief (Gass, 1989b). Those who primarily see the pain often focus their attention on the damage already done and expend much of their energy expressing anger, sadness, and depression, and their coping strategy often involves withdrawal, self-blame, and feeling overwhelmed. Those who see their loss as a threat are aware of the stress but are uncertain about their ability to deal with it. The death of their loved one means that they see other losses that are likely to follow. Their coping strategies usually include fear and worry about future threats to their lives. Rather than focusing their energy in broader ways to make their adjustment easier, they often engage in wishful thinking. The bereaved who see their loss as a challenge recognize the stress and the need to adapt. They assess their strengths, limitations, and needs and pursue a course of action that will allow them to learn and possibly grow from the experience. Having pride, self-confidence, motivation, and some skills in carrying out the many tasks of daily living helps the bereaved to define the situation as a challenge and follow a more problem-focused approach to adjustment (Lund, Caserta, Dimond & Shaffer, 1989). Lazarus (1966), Folkman, Lazarus, Dunkel-Schetter, De Longis, and Gruen (1986), Pearlin and Mullan (1992), and many others have advanced theory and research on stress, appraisal, and coping, and the perspective continues to make very important contributions to understanding bereavement.

7.05.5.3 Stage and Task Models

Ever since Kubler-Ross (1969) proposed the well-known stage model of the dying process, it has been applied to many discussions of how people deal with problems and life crises. The dying person was seen to pass through a naturally occurring sequence of experiences beginning with denial and progressing through anger, bargaining, depression, and eventually culminating in acceptance. Because bereaved persons and many professionals became familiar with the stage model developed by Kubler-Ross and they could see many similar emotions, thoughts, and issues expressed during the course of bereavement, it seemed only natural to apply the sequential and progressive stages to bereavement.

While research has identified and confirmed that bereaved persons experience many of the same kinds of emotions, thoughts, and behaviors presented in the stage models (Aiken, 1994; Hardt, 1978; Parkes, 1987), the overall bereavement process appears to be much less orderly, sequential, and uniform than these models suggest (Lund, Caserta, & Dimond, 1986; Wortman et al., 1993). For example, some bereaved persons report many years after the loss that they sometimes feel the sadness, pain, and regret that they experienced in the first several weeks (Lund, 1989a). The stage models have contributed to our knowledge about bereavement because they have helped to identify parts of the complex process and provided a foundation for further study.

Similar to the stage models and building on some of the concepts from other theories is the idea that adaptation requires the bereaved person to accomplish or complete specific tasks. Worden's (1991) "tasks of mourning" approach is an example. His work is based on the assumption that grief is work, requiring both emotional and physical energy to complete. He suggests that it is important for the bereaved eventually to accept the reality of the loss, to experience the pain of grief, to adapt emotionally and socially to an environment in which the deceased is missing, and to relocate psychologically the deceased person in their life and move forward. The notion of "relocating the deceased" recognizes the value of keeping memories alive and not assuming that the bereaved should forget the importance of their past relationships. While many other specific tasks can be added to his model, it does provide a very useful approach in helping bereaved persons. The task-oriented approach highlights the importance of being active and learning new skills rather than simply being passive and allowing time to pass and heal the wounds of grief. Worden's book is highly recommended reading for clinicians and researchers.

7.05.5.4 Other Theories

A wide range of theories from social, behavioral, and health sciences have been used to understand specific aspects of grief and bereavement but most of them have not been systematically tested in research. Some of the theories have received only limited attention even though they have considerable promise in explaining and predicting bereavement behaviors and helping bereaved persons through the process. For example, family and systems theories, symbolic interactionism, the health belief model, and the theory of reasoned action have much to add but have not been extensively used in research or practice.

Family and systems theories (Olson, Sprenkle, & Russell, 1979) are relevant to bereavement because bereaved people are members of nuclear and extended families and their lives take place within functioning systems. People do not live in total isolation from families, groups, and organizations, and their experiences within these units are important parts of the broader bereavement context. An 80-year-old widow is impacted by how other family members grieve the death of her husband, who also was a father, grandfather, uncle, and brother. Just like individuals, families grieve. Some family members provide strength and support to one another and other families create more conflict and tension during bereavement (Worden, 1991). Systems theory recognizes that people are parts of larger systems and individual lives consist of various functioning parts as well. Anger and depression following bereavement can easily carry over from the home to the workplace and many other social settings, thereby impacting and further complicating other relationships.

Symbolic interaction theory, which comes from the discipline of sociology, has much to offer the topic of bereavement (Lund, Caserta, Dimond, & Gray, 1986). This theory emphasizes the importance of social interactions with others and how they shape a person's self-concept or identity which in turn, influence behavior. Bereavement losses have the potential of altering a person's interactions and self-concepts and ultimately bereavement adjustments (Worden, 1991). From the field of health education, the health belief model (Rosenstock, 1990) and theory of reasoned action (Ajzen & Fishbein, 1980) are examples of conceptual frameworks relevant to bereavement. Both are applicable to examining the way bereaved persons make decisions and what they take into account to decide a course of action. Bereavement can very easily lead to neglect of one's own health. These approaches suggest that a broad range of factors including messages in the media can influence bereavement behaviors by identifying healthy behaviors to pursue and stressing the likelihood of positive outcomes that will follow. Grief requires considerable energy so good nutrition and regular exercise can be very helpful during the bereavement process (Lund, 1989a).

Finally, the most prominent theories in the field of gerontology have relevancy to understanding bereavement but they have not received much attention. Disengagement (Cumming & Henry, 1961), activity (Havighurst, 1968), continuity (Atchley, 1989), and age stratification (Riley, 1971) theories have contributions to make and hopefully, in the future, they will be examined and tested in research. Disengagement theory would suggest that those who were already gradually withdrawing from society will have less difficulty during bereavement than those who have not yet begun the process of withdrawal. The bereavement experience would not seem as abrupt to them. Activity theory would argue in favor of maintaining relatively high levels of physical activity during bereavement because it will help create greater life satisfaction and well-being. Continuity theory would suggest that the best course of action during bereavement would be to continue doing most of the things that one had always enjoyed. Age stratification theory could be used for a better understanding of why age might influence bereavement adjustments and that people in different age cohorts have different needs during stressful life transitions. An excellent reference resource for more information about these and other gerontological theories is *Social Gerontology* (Hooyman & Kiyak, 1996). In short, theory helps to inform and guide research and we need considerably more of both theory and research to improve our knowledge about grief and bereavement.

7.05.6 FEATURES OF THE BEREAVEMENT PROCESS

Research on bereavement, and particularly studies which examine predictors of outcomes, has considerably increased since the early 1980s. Some research investigators have waited many weeks and months to interview bereaved persons and others have obtained information only days after the death occurred (Stroebe & Stroebe, 1987). Nearly all of the early research studies avoided contacting bereaved persons during the first six months of the process, assuming that the bereaved persons would be too upset to participate. Later studies revealed that was not necessarily the case and by waiting too long much valuable information was lost (Lund, 1989b). Some studies followed bereaved persons for several years to examine long-term outcomes but most projects obtained information at only one point in time, providing only a limited picture of the process (Stroebe et al., 1993b). These cross-sectional studies did not adequately capture the many dynamic aspects of the process.

Only few investigators have included nonbereaved control groups, even though it is valuable to be able to compare the thoughts, feelings, and behaviors of bereaved persons with those who are not experiencing death-related bereavement (Lund, 1989a; Stroebe, Hansson, & Stroebe, 1993). In fact, nonbereaved control groups are needed to help determine what effects are most likely attributed to bereavement rather than pre-existing conditions. The ideal study design would include before and after bereavement measures to assess the effects of bereavement most directly, but these studies are expensive and lengthy. Research has also included more women than men, more adults than children, and more Caucasians than non-Caucasians. Therefore, much of what we have learned from research has been limited to specific populations. Even with these and other limitations, research has improved our understanding about grief and bereavement. It is not possible to review all or even most of these findings but five of the most important general conclusions are presented here.

First, bereavement is very stressful but many people manage their losses with considerable resiliency. In the case of spousal bereavement, the majority of research participants (72%) reported that their loss situation was the worst and most stressful thing that had ever happened to them (Lund, 1989b). The death of a child also creates stress and is particularly difficult because children are expected to live longer than their parents (Rubin, 1993). Among adults, it is disturbing when both parents are deceased because it means that their own generation in the family is now the most senior. The death of a spouse, parent, or child almost always brings out thoughts of mortality and death among the survivors. In Western culture, thoughts about the inevitability of death are usually troubling because, as mentioned in the introduction to this chapter, we have not openly discussed death. Some researchers have attempted to identify how many people continue for several years having major difficulties that interfere with their daily lives. It has been estimated that between 15 and 25% will need some kind of professional help with their bereavement adjustments (Lund, 1989a; Lund, Dimond, et al., 1986).

Even though bereavement is extremely stressful, it is somewhat surprising to know that many people are very resilient and able to restructure their lives in ways that allow them to find enjoyment again (Caserta & Lund, 1992b; Cleiren, 1993; McCrae & Costa, 1993; Murrell, Himmelfarb, & Phifer, 1988). One study (Caserta & Lund, 1992b) found that older bereaved spouses rated their stress levels in the range of 5.0–5.5 (on a 1–7 scale) during the first two years of bereavement. However, the currently married, nonbereaved control subjects indicated that their expected stress levels would range from 5.8 to 6.0 if they were in that same spousal bereavement situation (Caserta & Lund, 1992b). These data suggest that it is possible that many older adults will cope more effectively with bereavement than they expect. These research findings also help direct our attention to those 15–25% who are most distressed and unable to manage their bereavement losses alone and also recognize that not all bereaved persons will need professional assistance (Murrell et al., 1988; Wortman & Silver, 1989). These issues are discussed in further detail in the next section of this chapter.

Second, there is considerable diversity among and within bereaved persons (Levy, Martinkowski, & Derby, 1994). Not all people experience the same feelings, thoughts, and actions as they move through the process. For example, a 65-year-old widow in a research project described herself in the following way four weeks after her husband's death: "I am a very lonely person. Lousy, all washed out, despondent, feel deserted, angry, hurt, hopeless, alone, mixed-up, cannot concentrate, very emotional, very tired, cry a lot, hateful, very bitter, misfit, nobody, very miserable, very much of a loner." This same woman described herself in much the same troubled way two years into the bereavement process. She added that she was concerned about herself, and really hurt inside. She noted that she was sick of living alone and didn't care about life. In contrast, another 69-year-old widow described herself at six months after her husband's death as being "independent, excited about keeping busy, enjoying the company of others, and working in my yard and doing handiwork." Similar diversity in bereavement reactions is also found within each individual (Cleiren, 1993; Lund, Caserta & Dimond, 1993). It is not unusual to find a person simultaneously experiencing a very broad range of feelings and behaviors. For example, bereaved persons can feel angry, guilty, and lonely, yet at the same time feel personal strength and pride in how they are coping. A 70-year-old woman described herself at length as being busy, enjoying many different activities, and doing things with other people, but her final self-descriptive comment was that she still feels lonely. It is common for bereaved persons to experience simultaneously both positive and negative feelings (Lund, Caserta, & Dimond, 1986). For these reasons, it is difficult accurately to describe a bereaved person as doing very well or coping poorly. It is much more accurate to identify specific aspects or dimensions of people's lives where they are in greatest need for assistance.

Third, a theme emerging from recent studies is that of being more cautious in using the terms "normal" and "abnormal" to describe grief or bereavement experiences (Lund, 1993). Individuals may experience and express themselves in a variety of ways during bereavement. Research has shown that what would have been considered outside the realm of "normal" grief several years ago may now be considered a normal part of the process. For example, talking to a deceased spouse was previously thought to be abnormal or even pathological, but recent research findings show that this is actually a very common practice among bereaved spouses, and it is now often encouraged as a therapeutic technique related to reminiscence or relocating the deceased in the life of the bereaved (Worden, 1991). When we learn from a community-based sample of bereaved research subjects that they regularly talk out loud to their deceased spouses and appear to be coping relatively well, it suggests that the behavior is not nearly so problematic (Lund, 1989b).

Rather than applying rigid labels such as "normal" or "abnormal," it is more appropriate to use terms such as "common" or "uncommon" to describe bereavement feelings and behaviors (Lund, 1996). Bereaved persons are far less stigmatized by being told that they are experiencing some uncommon feelings than by being told, "You are abnormal." In fact, Western culture values people for being unique and different from others. Clinicians, in particular, need to be cautious not to assume that being different is abnormal.

Fourth, recent studies have revealed that the bereavement process is more like a rollercoaster ride than an orderly progression of stages with clear time frames associated with each stage (Lund, 1996; Lund et al., 1993). The bereavement roller coaster is characterized by the rapidly changing emotions of grief; meeting the challenges of learning new skills; recognizing personal weaknesses and limitations; developing new patterns of behavior; experiencing fatigue, loneliness, and helplessness; and forming new friendships and relationships.

Research has been unable to identify clear time markers associated with these many ups and downs. In fact, the highs and lows can occur within minutes, the same day, week, or month. Fortunately, most bereaved persons experience a roller coaster ride that becomes more manageable over time, with fewer abrupt highs and lows. This gradual improvement may never lead to an end or resolution (Silverman, 1986), however, because many bereaved persons report: "You never get over it—you learn to live with it."

Fifth, loneliness and problems associated with managing the tasks of daily living are two of the most common and difficult adjustments for older adults (Lund et al., 1993). These problems are even more difficult for the spousally bereaved because their daily lives are closely connected with their spouses and they frequently become dependent on each other for conversation, love, and sharing of tasks. Loneliness is problematic because it involves missing, sadness, and a void that does not go away simply by being with or among other people (Lopata, 1973; Osterweis et al., 1984; Parkes, 1987). Many bereaved persons report feeling lonely but not being alone. In the case of experiencing the death of a parent, child, or sibling who may live many miles away, the bereaved often describe how lonely they feel when they realize they can no longer call their loved one on the phone or hear their voice again. In a study by the author, 70% of the bereaved spouses reported that loneliness was their single greatest difficulty during the two years following their partners' deaths (Lund, 1989a).

Unfortunately, most older adults have not learned to do many of the tasks of daily life that are important to maintaining their health, well-being, and happiness. Many older men have not learned how to prepare meals, wash clothes, and clean house because they left these tasks to their wives. Similarly, many older women have not learned how to do home repairs, maintain or sometimes even drive an automobile, and manage finances. Research has shown that these deficiencies further complicate the bereavement process because grief requires physical and mental energy which can be additionally depleted by worrying about how these tasks will be done (Lund, Caserta, et al., 1989). The lack of skills in daily living lends itself to a promising focus for future interventions because these skills can be easily taught. Hopefully, future cohorts of men and women will be better prepared and more skilled in a much broader range of tasks of daily living.

7.05.7 PREDICTORS OF BEREAVEMENT ADJUSTMENTS

It is very common to hear people say that the passage of time will heal the wound of grief, loss, or bereavement (Parkes, 1987; Silverman, 1986). This assumption is problematic and inaccurate because it implies that little or no effort is required to cope with the situation (Worden, 1991). Simply allowing time to pass is expected to bring about successful adjustment. Although it is a fact that with the passage of time most bereaved persons experience less difficulty and make more positive adjustments, it is important to recognize that it is what people do with their time that has the most direct impact on their outcomes (Lund, 1989a). Successful adjustments require active rather than passive coping strategies. The importance of being active and taking charge is integrated within Worden's task-oriented approach to grief (1991). Worden recommends this approach to clinicians because it involves an active coping strategy that fits well into a variety of interventions and it appears to be a more effective strategy than just letting time heal a wound (Silverman, 1986).

Another similar finding supported by research is that many bereaved persons have told others that it is most helpful to take one day at a time and to remain active, busy, and socially connected with other people (Caserta, Van Pelt, & Lund, 1989). Being physically and socially active during the process can help to reduce the feelings of despair, helplessness, loneliness, and being overwhelmed that often contribute to a long-term strategy of waiting—often in vain—for time to bring about healing. In addition to these active coping strategies, recent studies have documented the importance of having social support from others and opportunities for self-expression available, especially in the early months of bereavement (Dimond, Lund, & Caserta, 1987; Lund, Dimond et al., 1986; Schuster & Butler, 1989; Thompson, Gallagher, Cover, Gilewski, & Peterson, 1989). Some of the most difficult and stressful bereavement experiences occur in the first few months when grief issues are especially intense (Wortman et al., 1993). The quality of social support from friends, neighbors, and family is more important than the quantitative dimensions of support and it appears that older spousally bereaved persons tend to rely increasingly more on neighbors and friends because they are most convenient to contact (Dimond et al., 1987; Lund, Caserta, Van Pelt, & Gass, 1990; Schuster & Butler, 1989).

Research has also shown that how a person copes with loss early in the process appears to be one of the best predictors of long-term coping (Levy et al., 1994). Those who report that they are doing quite well during the first couple of months usually cope better than others a few years later (Lund, Dimond et al., 1986; Wortman & Silver, 1989). Bereaved persons therefore are likely to benefit most from social support that they receive during the first two to eight weeks and from opportunities to express how they feel at this time. The first couple of months are most critical because that is when new patterns of behavior are developed and the adjustments that are required can be overwhelming. Early social support, therefore, is most beneficial (Schuster & Butler, 1989; Trunnell, Caserta, & White, 1992). Bereaved persons most value the support provided by those who allow them to openly express anger, sadness, and other emotions without passing along advice and counsel (Caserta, Van Pelt, & Lund, 1989; Dimond et al., 1987; Vachon & Stylianos, 1988). It is important for the bereaved to know that their reactions are common and that others respect their feelings and care about their well-being. People can be most supportive by being good listeners. This also relieves pressure that many people impose on themselves by believing that they need to say things that will make everything better. Such bereavement-eliminating messages do not exist. Self-help groups for bereaved persons provide good opportunities for self-expression, particularly for those who do not already have someone in whom they can confide (Lund & Caserta, 1992). These support groups vary considerably in quality and effectiveness but they do have the potential of providing some valuable sources of support (Lieberman, 1993).

The importance of internal coping resources is supported by research (Ben-Sira, 1983), that has focused on the role of self-esteem (Lund, Dimond et al., 1986) and self-efficacy (Bandura, 1982; Goldfried & Robins, 1982; Parkes, 1987). Both concepts represent personal coping resources that individuals develop throughout their lives. Self-esteem refers to the positive or negative judgments or evaluations that one makes about self-worth. In addition to being a husband or wife and a father or mother, we usually make assessments about being good or bad in the way we perform these roles. Self-efficacy refers to one's ability to meet the changing demands of everyday life and feeling confident to do so. Not all of us feel equally able to manage difficult and challenging situations, particularly bereavement, which requires a broad range of skills and confidence in being able to develop and use them.

The way people feel about themselves and how skilled they are in managing the many tasks of daily—living maintaining a household, paying bills, driving a car, knowing how to access resources, and so forth—will influence how effectively they adjust to the loss of a loved one (Lund, Caserta, et al., 1989). Men and women in today's older age cohort are highly deficient in predictable skills, with men not being well prepared to do shopping, cooking, and cleaning and women being unskilled in financial matters and home repairs. People who develop positive self-esteem and competencies such as social, interpersonal, and instrumental skills are likely to have more favorable bereavement outcomes than those who develop negative self-images and lack self-efficacy. The need to be skilled in the tasks of daily living is important to bereaved people of all ages (Goldfried & Robins, 1982). Worden (1991) describes one of his four tasks of mourning as adjusting to an environment in which the deceased is missing. Learning new skills is considered to be essential to this part of the adjustment process.

Self-esteem and self-efficacy are highly interrelated because people who have confidence and pride in themselves are usually more motivated to learn new skills, and the process of becoming more competent in daily life itself creates more positive self-esteem (Lund, Caserta et al., 1989). Bereaved persons with these positive characteristics are likely to cope quite well because they will not be content with a passive approach to coping and simply waiting for things to get better. People with high self-esteem are more likely to believe that they deserve to feel better and have the desire to at least try to engage in new activities and pursue interests that they have always had. Conversely, bereaved people who never developed these personal coping resources are likely to experience long-term difficulties because they are more inclined to believe that they deserve to remain depressed, lonely, and incapacitated. One research subject said, "Things are terrible, I feel awful but who cares." These people tend to feel overwhelmed and take few, if any, constructive actions on their own behalf. In short, the three best predictors of how older adults experience bereavement are self-esteem, competence in managing tasks of daily living, and opportunities for self-expression (Lund, Dimond et al., 1986). When bereaved older adults are high on these three traits they are much more likely to manage quite well, and adults who are lacking all three are at considerable risk of having long-term difficulties. These factors are likely to be similarly important to people of all ages (Lund et al., 1993).

While it is extremely difficult to summarize briefly the growing and increasingly complicated research literature regarding the many factors that might predict bereavement outcomes, it is appropriate to note that many variables that were expected to be important have not been consistently related to the adjustment process. For example, research has not found large differences in adjustments between those who experienced expected or sudden death situations (Faletti et al., 1989; Hill, Thompson, & Gallagher, 1988). The general expectation has been that it is much easier to manage a bereavement loss if it was anticipated. Unfortunately, there do not appear to be substantial benefits from knowing that a loved one is dying because when the death actually occurs it still sets in motion the most profound parts of the bereavement process which include dealing with loneliness, depression, and managing the numerous tasks of daily living. When a death is sudden and unexpected, the bereaved survivors are likely to feel more intensely the grief-related emotions, but when these gradually subside, the long-term process is quite similar to those who expected the death (Lund, l989a). If there are benefits from anticipating the death, they are most likely to be attributed to what people do with their time while they anticipate the death. The key element to realizing any benefit is the preparation, not for the death itself, but preparation for learning to do some of the many things that will be required after the death such as learning to do the laundry, cooking, home repairs, and other tasks of daily living. Developing new skills and "having affairs in order" can be helpful to bereaved persons of all ages because energy can then be focused on the grief work that needs to be done (Worden, 1991).

Research comparing bereaved persons from different religious membership groups, with unique religious beliefs and various degrees of religiosity, has revealed that these variables might create some unique bereavement experiences but they do not predict very well the major outcomes such as depression, loneliness, morale, life satisfaction, and a variety of other physical and mental health measures (Falleti et al., 1989; Gallagher, Lovett, Hanley-Dunn, & Thompson, 1989; Lund et al., 1993). It is possible that with different measures of adjustment these religious factors might be more influential but current research points out that these and other factors may be less important than previously expected. The degree of religious activity did, however, emerge in some research to be associated with bereavement adjustment with the more religiously active coping more effectively than the less active (Lund et al., 1988). This finding is consistent with other research that has shown an advantage to bereaved persons who make an effort to remain more socially active and to keep busy (Caserta, Van Pelt, & Lund, 1989). For many older adults, their religious participation can be a very important, convenient, and consistent source of activity that offers social contact, informal support, and a meaningful use of time.

Another important finding to emerge from research is that many older spousally bereaved persons find themselves in a dilemma wherein they must make decisions either to please themselves or others (Caserta, Van Pelt, & Lund, 1989; Dimond et al., 1987; Lund et al., 1990). It is not uncommon for some adult children to exert considerable pressure on their grieving parent to sell the house, get away from the memories, move closer to others in the family, sell the car, or simply do what they expect of them. In most cases, the bereaved older adult does not want the parent/child roles to reverse where they feel pressure to do what their children want them to do (Lund et al., 1990). Most adult children typically have good intentions but sometimes get carried away with trying to take away their parent's grief and make everything instantly better. As research shows, there are no quick solutions to the many adjustments that need to be experienced.

The pressure to conform to the desires and wishes of others, including the deceased, happens often enough that it can be referred to as "grieving according to the expectations of others" or even, "grieving according to the expectations of the deceased." One very common example of doing or saying what others expect occurs when an adult child visits a grieving parent and asks how he or she is doing. Our research interviewers have heard many of these bereaved parents say that they simply tell their children that they are doing fine because they know that is what their children want and expect to hear. They say that they do not want to trouble their children with the truth. They also report feeling that they need to project an image of strength to their children, neighbors, and family. Another interesting example was a bereaved woman who told an interviewer that she wanted to continue a friendship that she had with another man but felt that others would not approve of her spending time with him. She and her deceased husband had been lifelong friends with this man and his deceased wife. They had done many things together as couples. Now that they had both been widowed they wanted to continue spending time together. This woman made it clear to the interviewer that they were "just friends, nothing sexual going on." Rather than living according to their own expectations they made the effort to conceal from others that they were spending time together. Her male friend would wait until dark to visit and would park his car around the block and sneak through a neighbor's backyard to get to her house. As she described the strategy, the interviewer noted that she was embarrassed about the behavior but did not know how she could be more open about the relationship for fear of what others might think.

The deceased often continue to play important influential roles in how the bereaved survivor makes decisions about what is appropriate or not (Troll, Miller, & Atchley, 1979). Some bereaved spouses participating in research studies have said that they were very reluctant to do things that their deceased partners would not approve and that they were struggling with a decision or had already decided in favor of their deceased spouse's wishes. Most commonly, the decisions were regarding what to do with personal belongings and household items, forming new friendships, selling the house and moving to another area, returning to old hobbies and interests, and the purchase of clothing, furniture, and automobiles. One of the more interesting examples was a widow in a research project who described the very serious dilemma that she was having while trying to decide what to do with her husband's favorite friend, the dog. She indicated that she had always hated the dog and would love to get rid of it. Now that her husband was dead she had the opportunity to give the dog away. But, as she considered her choices she now felt that her deceased husband would be very upset if she did not keep and care for his companion. The widow did not take this matter lightly and chose to keep the dog even though her preference was to end the relationship. Until they are actually in the bereavement process people do not realize how difficult some daily life decisions can become. What appear to be rather simple choices are in fact complicated by the reality that others' opinions and expectations create considerable pressure. Although statistical data are not available regarding this, it is very likely that those who are bold enough to live more according to their own expectations will make the many bereavement adjustments with greater satisfaction than those who favor doing things primarily to please others (Caserta, Van Pelt, & Lund, 1989). Many older adults will need validation that it is acceptable for them to do things consistent with their own wishes, but, at the same time, know that others may disagree with their choices. Bereaved people will need to work through these kinds of dilemmas many times and discover what works best for them.

The predictors of adjustment to bereavement are similar for both men and women and for young and older adults (Lund, Caserta, & Dimond, 1986). Age and gender are not the most influential factors in the course of bereavement (Lund et al., 1993). What is of greater importance is to develop positive feelings about oneself early in life, continue to enhance these views over the life course, and develop skills that help one to meet the changing circumstances and demands of daily living (Lund, 1989a; Worden, 1991). People with these traits are more likely than others to adjust well to nearly any major life stress or transition (Goldfried & Robins, 1982; Hooyman & Kiyak, 1996). Human development is a lifelong process. In the case of late life bereavement, the developmental process is challenged. During this transition period, the bereaved person can remain physically, psychologically, and socially disrupted or can emerge with a sense of growth from learning new skills, becoming more independent, and developing a clearer self-identity.

7.05.8 WORKING WITH THE BEREAVED

Although bereavement is one of the most stressful experiences that occur in our lives, we should not conclude that most bereaved persons will need help with their adjustment process. Research has shown that many bereaved persons do not want or need intervention services (Levy, Derby, & Martinkowski, 1993; Lund et al., 1985). Most researchers estimate that between 15 and 25% of the bereaved will experience considerable long-term difficulty and may require major forms of assistance from others (Lund, 1993). This point is important to recognize because many clinicians and other service providers assume that most older bereaved persons are depressed, socially isolated, and incapacitated by their loss. In fact, gerontologists have reminded us that the majority of older adults do not fit the general stereotypes of being dependent, frail, poor, lonely, and in poor health (Hooyman & Kiyak, 1996). The research evidence does not support these and other assumptions, although certainly some bereaved persons are depressed, isolated, and incapacitated (Wortman & Silver, 1989). In fact, as mentioned previously, older adults are quite resilient and find ways to manage the many losses that they experience throughout their lives (Cleiren, 1993; Lund, 1993; Murrell et al., 1988; Worden, 1991).

The tasks for those developing intervention services are many, and among their first should be an attempt to reach those who are at greatest risk—to seek them out rather than simply announcing the existence of the service—and encourage their participation by explaining how and why the service will be helpful. It is absolutely critical to recognize that many, perhaps most, of the potential population of bereaved persons will not want to participate (Caserta & Lund, 1993; Lund et al., 1985). This can be discouraging to those who are committed to the value of their services, but their motivation to continue their efforts will probably be less adversely affected if they anticipate the lack of enthusiasm among many potential clients. For example, only 44% of the bereaved spouses who completed a study by the author said that they would have liked the opportunity of attending self-help groups (Lund et al., 1985). Later in another study only 27% of those assigned to self-help groups actually agreed to participate (Lund, Redburn, Juretich, & Caserta, 1989). For those who need assistance but are reluctant, it is often beneficial to obtain encouragement from others in the bereaved person's network, particularly physicians and important family members and friends.

Interventions need to be available early in the bereavement process and continue over relatively long periods of time (Horacek, 1995; Schuster & Butler, 1989; Trunnell et al., 1992). As discussed previously, there is a good deal of research evidence suggesting that the first few months are the most difficult and that early adjustments will influence outcomes much later (Caserta & Lund, 1993; Wortman et al., 1993). Also, because bereavement may last for many years and some people may not be ready for early interventions, it would be most helpful to have services available over long periods of time so that they may obtain the appropriate help when they are most ready to receive and benefit from it (Faletti et al., 1989). Others may require intervention or assistance for long periods of time but dependency on any particular form of help is not desired (Silverman, 1986).

Because the impact of bereavement is multidimensional, it is imperative that interventions offer comprehensive and diverse sets of services. It is unlikely that any one intervention will be capable of providing all that is needed, but each intervention should clearly identify which needs are being targeted in relation to the overall multidimensional process so that there is an awareness of what help is not being provided. For example, the death of a spouse in later life can impact emotions, psychosocial functioning, health, family life, interpersonal relationships, work, recreation, and financial situations. Therefore, those designing interventions which provide primarily an opportunity for self-expression (such as self-help groups) should recognize that some dimensions are not likely to be addressed (Shuchter, 1986; Shuchter & Zisook, 1993). Clinicians need to be aware of the full range of services that are available in their communities so their clients can obtain a unique set of diverse services to meet their unique needs. Ideally, all communities would have available a variety of interventions or services so that each person's unique skills, resources, and circumstances could be matched to the most appropriate set of services. While this is unlikely, we can at least strive to offer interventions with the broadest scope of impact. Therefore, whenever possible, it would be worthwhile to impact several dimensions simultaneously (Shuchter, 1986) by providing opportunities for self-expression and the enhancement of self-esteem; by teaching new skills to complete the tasks of daily living; by enhancing and mobilizing already existing social support networks; by providing education and assistance regarding health, nutrition, and exercise; and by encouraging social participation. Each of the predictor variables reviewed in this chapter can be integrated within nearly every type of intervention.

Behavioral competency interventions (Ben-Sira, 1983; Hill, Lund, & Packard, 1996) that identify and provide specialized training in daily survival skills can be of great value for several reasons. First, such training equips bereaved individuals with the special expertise they need to manage the tasks that had been performed by their deceased loved one. Second, successful mastery of new skills builds self-esteem and reinforces beliefs about personal competence. Finally, the process of training provides informal opportunities for the individual to socialize and interact with others while learning important life skills. Skill training interventions offer an innovative approach with promise for helping bereaved older adults cope with issues of grief and mourning and prepare for healthy independent living.

Various intervention formats and professionals are needed to ensure that appropriate services are available. Not all people experience bereavement in the same way; similarly, not all people will use or benefit from the same interventions. In terms of format, some people will only want to have a one-on-one type of intervention. This might be because they feel the uniqueness of their situation can be dealt with more effectively one-to-one, because they are reluctant to express personal and sensitive feelings in group situations (Silverman, 1986). Others have reported that they particularly enjoyed being in a self-help group because they learned from others, recognized some commonalities in their situations, and enjoyed the socializing and friendships which developed (Lund & Caserta, 1992; Caserta & Lund, 1996).

Self-help support groups are a commonly used intervention with older adults (Lund, Redburn et al., 1989). Such groups generally consist of bereaved individuals who voluntarily meet to discuss issues and problems associated with their situation (Lieberman, 1993; Lieberman & Videka-Sherman, 1986). Participants can experience hope, learn new ideas and problem-solving strategies, improve skills for developing social relationships, become less lonely, explore new role definitions, discover that others have similar difficulties, and receive additional social support and encouragement. Belonging to a group and sharing feelings of fellowship and solidarity have been helpful to many older adults. Many of the general benefits of various self-help groups are especially relevant to bereaved older adults. Group members often discuss ways to alleviate the feelings of loneliness, social isolation, and hopelessness that accompany widowhood. Members also have opportunities to meet new people, participate in social activities, and form new friendships (Caserta & Lund, 1993). In addition, many bereaved spouses experience difficulties managing tasks of daily living such as meal preparation, house cleaning, yard maintenance, and transportation that were performed previously by the deceased spouse. Group members regularly share information, advice, and resources about these common problems. Finally, self-help groups are less expensive than most alternative services and are often attractive to individuals who are reluctant to use the services of mental health professionals and agencies. Support groups are not without their share of problems because they require clear goals, well trained leaders, and realistic expectations. Poorly run groups can become overly depressing and ineffective. Good outcomes do not often happen by chance but are the result of careful planning and good leadership (Lund, Redburn et al., 1989).

Many people have skills and expertise which are well suited for helping the bereaved. Silverman (1986), who developed the widow-to-widow program, has shown that widows are quite capable of assisting each other. An experienced widow can reveal to the new widow that she has been there and knows how it feels to grieve. Also, there are important contributions that can be made by researchers, gerontologists, psychologists, psychiatrists, physicians, social workers, nurses, occupational therapists, counselors, clergy, and many other professionals, including social scientists, lawyers, accountants, educators, and direct service providers. Again, because bereavement has a multidimensional impact, interventions can be developed by many different professional and trained team members. Other bereaved persons can provide a sharing of experiences while trained persons assist with legal, financial, health, spiritual, and educational issues. A multidimensional team approach is highly recommended because it will increase the likelihood of developing interventions which address the diversity of needs and lead to greater success.

7.05.9 SUMMARY

Bereavement is a common and natural experience that we all share. Unfortunately, many people are not well prepared for the pain, threats, and challenges that it presents. Because bereavement occurs in broader contexts, we do not all have the same personal and social resources available (Caserta & Lund, 1993), or have the same experiences and needs. What appears to help one person may have an entirely different impact on someone else. The best way to be prepared to help bereaved persons is to be educated about the process, assess the context in which it occurs, become familiar with a wide range of helping resources, and be patient, a good listener and nonjudgmental.

One final suggestion concerning future research and clinical practice is the need to be creative and work in interdisciplinary teams whenever possible. Being creative means that while looking at the same thing you are able to see something different, perhaps many different things. Good quality research and interventions are not always the result of following a "cookbook" approach where we simply look up the issue or problem and find the recipe to resolve it. In order to ask the most interesting and important research questions, decide on the best methodology, or develop and offer the most effective intervention, we need to be very creative. We need to be willing to take a risk and modify the way we mechanically make research and treatment decisions. One of the best ways to be more creative is to work in interdisciplinary teams.

Researchers and clinicians are trained within specific disciplines and learn to favor specific research designs and intervention strategies. Over time, each professional's training becomes his or her area of expertise and there is a natural tendency to define questions and issues in a way that leads to using the same methodologies and practices. Abraham Kaplan, a philosopher of science, refers to this rigidity as "the law of the instrument" (1964, p. 28). He states that if you give a young boy a hammer, everything he encounters will need pounding. If a researcher or clinician exclusively uses only one theory, one methodology, or one counseling strategy then other techniques and strategies are ignored. If they cannot become skilled with more than just a single approach to their work (the hammer) it is even more important for them to work collaboratively in interdisciplinary teams so that other tools, strategies, perspectives, and methodologies are used. One of the best ways to be creative is to assemble a team of investigators who represent diverse and needed areas of expertise. When clinicians and researchers from medicine, pharmacy, nursing, social work, social and behavioral sciences, and other disciplines work collaboratively the end results are much greater than just the sum of the parts. New methodologies, techniques, and strategies will result from the creativity that is enhanced by working in multidisciplinary teams.

Death and other bereavement-related losses will continue to surround our daily lives, offering us choices to learn from these experiences or to use them to be better prepared for our personal losses and our professional work. Although we have learned much from research and clinical practice there are substantial gaps in our knowledge. Much creative and pioneering work remains for those who have the interest, expertise and enthusiasm to learn more about grief and bereavement and to apply this knowledge to make a difference in people's lives.

7.06.1 INTRODUCTION

With age comes increased interaction with the legal system in our society. Because of increased prevalence of cognitive impairment with age, psychologists are often expected to address legal concerns that result from potential cognitive impairment. Concerns about the capacity of the older individual to make autonomous decisions surface frequently, in part because of the greater decisional burden that age-related health problems place on older adults. Thus, assessing capacity for decision making is a large and growing area of geropsychology.

An understanding of decision-making ability of older adults is dependent upon a number of different fields of inquiry and several different areas of literature. This chapter is organized into five main sections. The first summarizes the development of the current doctrine of informed consent and the literature on informed consent with older adults is briefly reviewed. In the second, the concept of competence is examined more closely, beginning with a brief history of the development of theoretical and empirical work on decisional capacity. In section three, the forensic psychology and cognitive psychology contributions to the concept of capacity are compared. In the fourth, competence assessment is discussed. In the fifth section some of the issues raised by work with older adults is explored in the context of a specific policy, the Patient Self-determination Act. Finally, additional areas relevant to older adults' decisional capacity are highlighted.

7.06.2 INFORMED CONSENT

7.06.2.1 Brief History of the Doctrine of Informed Consent

Investigations of the adequacy of informed consent procedures usually involve reference to measurable components of the construct of "informed consent." Three components are identified in a widely accepted model of informed consent, a model which derives from legal requirements: there must be adequate disclosure of relevant information, the choice must be voluntary, and the individual must be competent to make the decision (Appelbaum and Grisso, 1988, 1995; Faden & Beauchamp, 1986). While some controversy surrounds all three of these elements, competence has been the most difficult to define and measure, and has generated the most discussion. Views of competence in the late 1990s will be examined in the next section. First, however, the development of the current view is described.

The legal history of informed consent in the USA can be traced back to eighteenth century Britain, where the King's Court ruled that medical surgery performed without the consent of the patient constituted a "tortious assault." More recently, a 1905 Minnesota case (*Mohr v. Williams*) established that surgery performed without permission constituted a battery. The significance of this ruling was that the patient, and not the physician, was to determine choices as to physical interference with an individual's body. Further affirmation of this principle of self-determination was recorded by Justice Benjamin Cardozo, in an opinion written in 1914: "every human being of adult years and sound mind has a right to determine what should be done with his own body" (*Schloendorff v. Society of New York Hospitals,* 1914).

Two cases refined the concept of "informed consent." In the 1957 case of *Salgo v. Leland Stanford Jr. Board of Trustees*, the court ruled that physicians had a duty to disclose information about the risks and alternatives of treatment. In the 1960 case of *Natanson v. Kline*, the court ruled that the patient must be provided with a certain amount of relevant information; it was no longer sufficient for the patient to consent to or decline treatment. At that time, the legal standard for the amount and kind of information provided was based on a professional practice standard and was, therefore, set by the medical community: "deviation from the standard of conduct of a reasonable and prudent medical doctor of the same school of practice as the defendant under similar circumstances."

In 1972, the case of *Canterbury v. Spence* shifted the determination of the legal standard for disclosure from the medical community to the patient. The patient was entitled to disclosure of information that any "average, reasonable patient" would require in deciding whether or not to consent to the procedure, and *not* disclosure based on a professional practice standard. This ruling is significant for its emphasis on patients' rights which, according to the court, "demands a standard set by law for physicians rather than one which physicians may or may not impose upon themselves."

By the end of the 1970s, legal developments required that patients be apprised of the nature and risks of a medical procedure by the physician. The concern of the law was that information was properly provided to the patient, the patient comprehended it, and the patient voluntarily consented to the procedure.

The cases reviewed above indicate the source of legal standards in the late 1990s for the information that providers are required to disclose, but the practical translation of these legal requirements to clinical situations is unclear. The law has paid less attention to the abilities an individual should possess in order to provide truly informed consent; such requirements are being explored more thoroughly in the field of psychology (and will be discussed more fully later).

7.06.2.2 Informed Consent and the Elderly

The elderly are a heterogeneous group (Stanley, Guido, Stanley, & Shortell, 1984), yet older adults are grouped together for the purposes of many policy initiatives. Besides policy precedent, there may be other reasons to examine older adults as a single group. In some studies, elderly subjects have demonstrated poorer comprehension of informed consent information than younger subjects (Stanley et al., 1984; Taub, 1980). Given historical differences in education level and vocabulary level between successive cohorts in the US, certain segments of the elderly population may be at increased risk for poorer comprehension of informed consent material.

To the extent that age differences continue to be manifest, and since end-of-life decisions occur more commonly among older adults than any other age group, elderly people may in fact present "unique ethical challenges" (Buehler, 1990) to health care providers. Before singling out a group for study, however, consideration must be made of the criteria involved in defining the group, and within-group heterogeneity must be acknowledged. While it is true that certain broad statements about a heterogeneous group like the elderly are of limited use (and may be ethically questionable (Cohen, 1996)), generalities do exist which justify the examination of elderly people as a separate group.

The process of obtaining informed consent from older adults may differ from obtaining informed consent from younger adults in important ways. For example, because of the prevalence of chronic medical conditions among older adults, disclosure and consent may be part of an ongoing process rather than just elements related to an acute episode. Chronic illness may change important features of the relationship between health care provider and patient for which informed consent laws were written.

Moody (1988) advocates a shift in emphasis from informed consent to the concept of "negotiated consent," in which emphasis shifts from a dichotomous variable view of consent (can the patient provide informed consent or not?) to a continuous variable view (to what extent can the patient understand this information and make an informed choice, over time?). Although originally conceived of in relation to long-term care settings, the concept of "negotiated consent" may be applicable in acute care settings as well, particularly for older adults with chronic conditions, re-admitted to the same facility multiple times.

7.06.3 COMPETENCE TO PROVIDE INFORMED CONSENT

Historically, legal applications of the term "competence" have provided inadequate specificity and have been underdetermined for research purposes (Appelbaum & Grisso, 1988). The limitations of legal conceptualizations of competence have prompted some researchers to examine the concept from a psychological perspective instead. Below, the evolution of definitions of the term "competence" are briefly reviewed. General aspects of definitions are presented first, drawing largely from the forensic psychology literature. In Section 7.06.4, contributions of forensic and cognitive psychology to thinking about competence are reviewed. The ways in which conceptualizations have been put into practice are discussed in Section 7.06.5.

7.06.3.1 Definitions of Competence

Definitions current in the late 1990s, are most readily understood when considered in relation to recent historical developments. These developments are briefly reviewed below, and Table 1 provides a summary of this discussion. As shown in the table, it is possible to trace a progression from early definitions which included a requirement that the choice be rational to later definitions which dropped the requirement for a rational choice ("Rationality" in the table) and added a requirement of awareness or insight ("Appreciation" in the table). Each of these individual definitional elements requires some explanation.

Definitions of competence have historically been tied to legal definitions of informed consent. Because proper disclosure of information is central to legal requirements for informed consent, early definitions of competence centered around understanding of the disclosed information. Roth, Meisel, and Lidz (1977) found most definitions required that "an individual must be able to comprehend the nature of the particular conduct in question and to understand its quality and its consequences" (p. 279). Appelbaum and Grisso (1988) identify understanding as "the concept referred to most often in legal cases and statutes" (p. 1635). As

Table 1 Elements of definitions of decisional competence from selected sources, 1977–1995.

	Definition Elements			
	Understanding	*Reasoning*	*Appreciation*	*Rationality*
Rationality-dependent definitions				
as noted in Roth et al. (1977)	X	X		X
Lidz et al. (1984)	X			X
Stanley et al. (1984)	X	X		X
Combination Definitions				
Miles (1989)	X		X	X
Draper and Dawson (1990)	X		X	X
Appreciation-dependent definitions				
Appelbaum and Roth (1982)	X	X	X	
Tepper and Elwork (1984)	X	X	X	
Kapp (1988)	X	X	X	
Appelbaum and Grisso (1995)	X	X	X	

Kelman (1982) states: "Voluntary, informed consent is illusory if the participants lack the capacity to evaluate the information" (p. 62). It is so central to competence, in fact, that "most researchers have implicitly assumed that an understanding of treatment information is the sole criterion of competence" (Tepper & Elwork, 1984, p. 205) . Understanding therefore appears as a standard in every definition of competence (see column 1 of Table 1). Of interest is the appearance of other standards and the rationale for their inclusion.

In general, earlier definitional systems included reference to a standard of reasonableness or rationality of the choice. Because of problems in separating politically or socially subjective standards of rationality from competence assessment, the rationality standard is often excluded from more recent systems, although rationality of the *reasons* for the choice is still included in many formulations of competence. Rationality of the reasons behind the choice requires both reasoning ability and some level of appreciation of the relevance of the decision to oneself. Rationality of reasons is a component of reasoning quality, and systems which include this criterion are listed under "Reasoning" (column 2) in Table 1. Systems which evaluate rationality of the decision itself are listed under "Rationality" (column 4). Those systems which attend to individuals' appreciation of the relevance of the information for their own situation (or at least acknowledgment of illness) are indicated under "Appreciation" (column 3).

As Table 1 indicates, definitions of competence tend to take one of two forms, labeled here as rationality-dependent and appreciation-dependent types.

7.06.3.1.1 Rationality-dependent definitions

One example of an early formulation is presented by Roth et al., (1977). They cite the following four standards as ones in use at the time of their writing: evidencing a choice, reasonableness of choice, rationality of reasons for choice (which requires an ability to understand), and actual understanding. Their presentation is not an endorsement, and in fact they point out some of the problems with each standard, particularly with the reasonableness standard.

Building from the earlier work of Roth and colleagues, Lidz et al., (1984) define competence as "the legal presumption that a patient has the capacity to comprehend the information the doctor discloses" (p.22). In addition to understanding of disclosed information, they cite rationality of the decision and rational reasoning ability as additional required elements.

Stanley et al., (1984) present a substantially similar definition to Lidz et al. they include comprehension, rationality of the choice, and quality of reasoning as required elements for competence. Of interest in their system is the criterion they use for evaluating quality of reasoning: evidence of weighing risks and benefits. This is a criterion that appears in later—and more sophisticated—systems as well.

7.06.3.1.2 Combination definitions

Like Stanley et al. (1984), Miles and Gomez Carlos (1989) define competence as "an ability to learn and repeat risks and benefits and make personal choices in light of that knowledge."

Also like Stanley et al., they include a decisional component in addition to an understanding component. Rationality of the choice is also part of his framework. An important difference, however, is that Miles and Gomez Carlos includes appreciation of the relevance of the information as a standard.

In 1990, Draper and Dawson presented their definition of competence to consent to treatment. Like Miles and Gomez Carlos's system, appreciation of the situation is included, but no reference is made to reasoning ability. Surprisingly, despite a warning to remember that "legal competence is not identical to rationality, that rationality is not a necessary condition of legal competence" (p. 286), rationality is included in their system, in which the rationality of the choice itself—rather than rationality of the reasons for the choice—is required for competence.

7.06.3.1.3 Appreciation-dependent definitions

Only those definitional systems that exclude rationality of the choice as a standard, and include appreciation of the relevance of the information for oneself are considered representative of the second definitional type, the appreciation-dependent definition. The appreciation requirement excludes as incompetent individuals with delusional thought about the relationship between the informed consent disclosure and their own lives. The appreciation-dependent definitional type is represented by the work of Appelbaum and Grisso (1995), Appelbaum and Roth (1982), Kapp (1988), and Tepper and Elwork (1984).

Most researchers agree that individuals out of touch with reality fall outside a credible definition of competence. The appreciation and rationality standards are both attempts to include a contact with reality requirement in a definition of competence. The rationality-dependent definition, by using rationality of the choice as the measure of contact with reality, allows for societal norms and evaluator subjectivity to intrude on the assessment of competence and it implicitly assumes that rationality can be objectively evaluated, or at least that there is an absolute standard of rationality. The appreciation-dependent type of definition requires no such assumptions. Competence is free to remain a relative term, accommodating idiosyncratic aspects of the individual's thinking, with the exception of delusional thinking. An individual needs to demonstrate some understanding of the disclosed information and some ability to think about that information in a rational manner. But individuals must also possess insight into the fact that informed consent represents a choice point: they must be aware that the disclosed information is relevant to the choice in question.

Kapp (1988) presents a system which includes rationality of reasons for the choice as a standard, but significantly he does not include a criterion of reasonableness of the choice. He labels his system a "functional approach" in which the focus is on individual ability. In addition to rationality of reasons, the following standards are cited as requirements: the ability to make and communicate a choice, the ability to reason about the choice, and understanding of relevant information and appreciation of the relevance of that information for oneself. Kapp's system is noteworthy because, like Appelbaum and Roth's (1982), it adds the dimension of appreciation of the situation.

Appelbaum and Grisso (1995) present an appreciation-dependent definition of competence as well. Understanding, rational manipulation of disclosed information (i.e., reasoning), and appreciation of the relevance of the disclosed information for one's own situation are all required elements. This particular definition will be discussed in greater detail in Section 7.06.5.1, below.

7.06.3.2 Other Considerations for Definitions

As discussed earlier, requiring that the reasons for a choice be rational still allows for objective assessment. Requiring that the *choice* be rational implicitly requires a subjective value judgment on the part of the assessor. Recognition of the interaction of social and legal requirements with definitions of competence represents an improvement in definitional schemes. For some, this interaction requires some means of minimizing the role of socially based values—like rationality—from competence determinations. One way is to use an individual-centered view of competence. An example of such a system is Drane's (1985) recommendation of the use of a sliding scale, in which the threshold for each of the relevant standards is a function of the nature of the situation. This relativistic position is also expressed by Katz, who recommends shared decision making (from Faden & Beauchamp, 1986); Moody's (1988) idea of "negotiated consent" (discussed above) is similarly individual-centered. In these views, an individual may be competent to make decisions at a low level, that is, when the decision does not require truly "autonomous action" (Faden & Beauchamp, 1986). Higher thresholds may be surpassed with assistance. Setting the appropriate threshold, however, involves moral judgments. While some researchers deal with the need for thresholds (e.g., Wang & Ennis, 1986), few acknowledge the dependence on socially determined, subjective standards.

A more complex view of competence is presented by Grisso (1994), in which he addresses the issue of threshold setting and subjectivity explicitly. He discusses four essential components of competence: functional, causal, interactive, and judgmental. The functional component centers around the extent to which an individual can "understand or do that which is relevant." The extent to which an individual fulfills this requirement can be assessed either functionally (in practice) or inferentially (based on clinical assessment). The causal component requires presence of a "causal explanation for any functional deficits." This component is an attempt to include objectivity in the definition. It stimulates exploration of potential causal disorders and it also brings attention to the remediability and relevance of those disorders. For example, if someone's competence is in question because of a diagnosis of Alzheimer's disease, to what extent do the consequences of that disease affect the individual's abilities? To what extent might some relevant consequences be corrected? The interactive component includes consideration of the individual's abilities in relation to the contextual demands on that individual. Grisso's interactive component is most similar to the context-specific competence described by Faden and Beauchamp (1986) and to the domain-specific competence of Sprung and Winick (1989).

Grisso's final component of competence recognizes the close relationship between individual-level and societal-level considerations. The judgmental component depends on societal norms, those criteria that society deems important in determinations of competence. The tension between societal obligations to protect individuals and societal obligations to respect individual autonomy characterize the judgmental component.

Legal and social context influences all competence-related activities. Like Grisso, Kopelman (1990) recognizes the impact of social and legal norms on definitions of competence; she states that competence cannot be defined without reference to those norms. The issue is best expressed by Faden and Beauchamp (1986) in their distinction between two senses of informed consent. To satisfy the first sense, an individual must be psychologically competent, meaning that relevant abilities are possessed. In the second sense, an individual must meet legal criteria (being over the age of majority, for example). The two senses may be assessed separately, but both are required under legal systems in the late 1990s. Their distinction between general and specific components of competence flows from this dichotomy.

Because of the confusion possible when applying general definitions of competence to specific situations, legal definitions are advancing from the general to the specific (Sullivan & Youngner, 1994). Grisso (1994) and Anderer (1990) note the trend in state statutes, and Appelbaum, Lidz, and Meisel (1987) observe that judicial decisions reflect this trend as well. The earlier definitions of competence are general, and thus are inadequate for application to specific situations. Attempts to refine and improve definitions of competence have resulted in attention to the dynamic nature of the abilities in question and their dependence on context for meaning (e.g., Grisso, 1994; Willis, 1996).

Other definitions also make the distinction between general and specific components of competence. Faden and Beauchamp (1986) say that competence is "the ability to perform a task," and this definition is invariant across all domains to which it is applied. This is the general component of the definition. They go on to note that criteria for determination of competence, however, vary by situation, and are therefore context-dependent. The dependence on context is their form of a specific component.

Sprung and Winick (1989) take a dual aspect approach to the definition of competence as well. Similar to Faden and Beauchamp's identification of a specific context-dependent competence, Sprung and Winick identify domain-specific incompetence. (Use of the term competence and incompetence is frequently mixed in most discussion, with incompetence implicitly assumed to represent the inverse of competence. This assumption remains unexamined, however, and arguably incompetence may be defined as something different from simple "noncompetence." For the purposes of this discussion, however, the focus remains on defining competence, and the term incompetence" is used only when the research in question uses that term.) However, Sprung and Winick's view differs from Faden and Beauchamp's in terms of the meaning of the general component. To Faden and Beauchamp, it is a characteristic of the definition which is general, that is, that all definitions of incompetence are similar because of their reliance on an inability. For Sprung and Winick, general incompetence means global inability. Individuals are incompetent in the general sense if they are unconscious or profoundly psychotic, for example. This latter view is more pervasive.

Lidz et al., (1984) make the distinction between two different types of incompetency in the same manner that Sprung and Winick do; general incompetence means global inability, and specific incompetence means inability to make a specific decision.

As Tepper and Elwork (1984) note, "development of an operational definition of any construct is, in part, a subjective endeavor" (p. 219), and as such will defy definitive resolution. Clearly, definitions of competence are evolving, accommodating increasing complexity and acknowledging the interaction between societal standards and individual abilities.

7.06.4 PSYCHOLOGICAL PERSPECTIVES ON COMPETENCE TO MAKE DECISIONS

In this section, psychological views of competence are examined in greater detail. The contributions of two distinct psychological perspectives to the question of competence are reviewed in detail: the forensic psychological view, which originates from legal requirements, and the cognitive psychological view, which originates from the study of human cognitive processes.

Both perspectives share a disciplinary emphasis of psychology, the science of the mind and behavior. The differences in the views will be reviewed further, but one critical distinction must be made before further examination. The forensic psychological perspective is concerned with "research that can lead to the development of improved and empirically based criteria for decision-making with respect to a number of difficult law and mental health issues" (S. Shah, quoted in Voit, 1995, p. 10). Competence questions are framed in terms of what relevant skills the law requires; the law is the springboard for investigation. In contrast, the cognitive psychological perspective is concerned with identification and measurement of cognitive processes such as problem solving, reasoning, memory, and knowledge representation (Craik & Salthouse, 1992; Datan, Rodeheaver, & Hughes, 1987). Most of the 1980s and 1990s definitions of competence reviewed above derive from a forensic psychological perspective. The next subsection expands on the meaning of a forensic psychological view, followed by a brief review of cognitive psychological perspectives on competence. Finally, the contributions of these two psychological views are compared.

7.06.4.1 Forensic Psychological Views of Competence

The forensic psychological view of competence is most often used by individuals with a combination of legal and psychological training. In most cases, these researchers have the express goal of enhancing psychological practice by attending to relevant legal issues and enhancing legal policy through empirical assessment. The forensic psychological view is distinguished from purely legal views by its emphasis on quantification of relevant variables.

One prominent feature of forensic psychological definitions is reliance on the term "decisional capacity" rather than "competence" as a means of improving specificity (Appelbaum & Grisso, 1988; President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research, 1983). As discussed in the preceding review of definitions, a trend towards increased specificity is evident. Similarly, the American Bar Association (1991) notes the evolution in the legal concept of competence, from a global conception to a conception based on functional abilities; the American Bar Association report even recommends use of the specific term "decisional capacity" (instead of the more global term "competence") in legal contexts.

The contribution of forensic psychology to definitions of competence is evident in the review of definitions presented above. For example, the forensic psychological view has advanced definitions from a simple, global level centered around understanding to a more complex, hierarchical set of standards or component abilities. The work of Appelbaum and Grisso (1995), Appelbaum and Roth (1982), Kapp (1988), and Tepper and Elwork (1984) all represent forensic psychological views. All share a sensitivity to the process of mapping legal notions of informed consent to actual situations. One of the main contributions of this work is the foundation it lays for assessment of legally based constructs in clinical situations. The assessment approaches developed within this perspective will be reviewed later in the chapter.

7.06.4.2 Cognitive Psychological Views of Competence

Cognitive psychology has made distinct contributions to the clarification of competence. Several caveats must be noted before reviewing this literature, however. First, "competence" has numerous meanings in cognitive psychology, only some of which relate to the informed consent component of interest here. For example, the subject index of an edited volume in cognitive psychology includes a listing for "competence" but says "see also Self-efficacy" (Lachman & Barrack, 1993). Similarly, in Sternberg and Wagner's (1986) volume *Practical Intelligence*, several different types of competence are referenced in the subject index, including cognitive, social, intellectual, and interpersonal. Applying a cognitive psychology perspective to the examination of competence to provide informed consent therefore requires vigilance regarding the concepts actually being discussed.

The literature on everyday problem solving has some important parallels to the development of the concept of competence to provide informed consent. Although definitions vary slightly, in general, everyday problem solving is defined as intelligence directed at practical problems, distinct from abstract or "academic" intelligence (Sternberg & Wagner 1986). Measures of academic intelligence have been characterized as holding little intrinsic interest for the individual, being disconnected from the individual's daily experience, and often having a single correct answer (Sternberg & Wagner). In contrast, practical intelligence has as a goal "the solution of problems which challenge the well-being, needs, plans, and survival of the individual" (Charlesworth, 1976, quoted in Sternberg & Wagner, p. 52).

Willis and Schaie (1994) list the following five aspects of everyday problem solving: relevant mental abilities and skills; domain-specific knowledge; understanding of personal circumstances and of interpersonal context; attitudes, beliefs, and preferences; and integration of these dimensions. An important feature of this type of problem solving is recursiveness, that is, solutions or decisions may be arrived at in a nonlinear manner (Willis, 1996).

Two of cognitive psychology's everyday problem-solving dimensions are notably absent from forensic conceptualizations, however. Within the forensic framework, the role of attitudes, beliefs, and preferences is not addressed, nor is the potential for recursiveness in the decision process. Arguably, legal requirements necessitate a single response on a single occasion, and the importance of attitudes, beliefs, and preferences to the decision is potentially minimized by this single-time focus: each may change over time, but if a one-time decision is the focus of the law, then at most the law will be concerned with the influence of each on the present decision. A single-time focus also obviates a temporally recursive perspective.

Among the core issues addressed by cognitive psychology are memory and attention, both of which are relevant to a consideration of competence. Not surprisingly, findings from cognitive psychology are immediately applicable to competence concerns. Salthouse (1996) notes that mental screening tests are one method of assessing "cognitive competency, and indirectly the capacity to make responsible decisions" (p. 36). Using the Mini Mental State Examination (MMSE, Folstein et al., 1975) as an example, he notes that comprehension, short-term memory, and the ability to attend and concentrate are among the skills assessed by the MMSE. These skills are the minimum needed for "reasonable decision making," and thus are applicable to views of competence. Salthouse identifies the main similarities between forensic psychology and cognitive psychology views of competence when he discusses competence assessment, which he says "should not only be context-sensitive or situation-specific but should also incorporate evaluations of the individual's comprehension and reasoning relevant to the decision" (p. 13).

Advances in conceptualizations of competence have led to attempts to assess competence empirically, since assessment follows from, and in some cases feeds back to, conceptualization. Assessment of competence is considered next.

7.06.5 ASSESSMENT OF COMPETENCE

Older adults are increasingly confronted with serious health decisions, yet little normative information about the decision-making abilities of older adults exists. The growth of the elderly population in the USA and the widespread availability of life-sustaining technology underscore the need for proper assessment of medical decision-making ability.

Assessment schemes depend on definitions of competence and the standards used to operationalize the concept. Several assessment schemes are examined below, and some of their problems are explored. Table 2 presents an overview of this discussion. As the table demonstrates, all systems reviewed here include at least some aspect of "Understanding." The systems differ in their attention to the other conceptual elements. Mental status is arguably an implied component of most, especially those which address memory and language elements explicitly. The rationality and appreciation elements are discussed for each example.

7.06.5.1 Assessment of Competence to Consent to Treatment

An example of an early competence assessment scheme is that of Stanley et al., (1984). Comprehension figures prominently, as does

Table 2 Conceptual elements addressed in the empirical assessment of competence (organized by type of competence).

	Conceptual Element						
	Mental status	*Understanding*	*Memory*	*Language*	*Reasoning*	*Rationality*	*Appreciation*
Type of competence							
Consent to treatment							
Stanley et al., 1984		X			X	X	
Wang and Ennis, 1986		X	X	X			
Draper and Dawson, 1990		X				X	X
Fitten and Waite, 1990		X			X		
Freedman et al., 1991		X	X	X	X		X
Janofsky et al., 1992		X					
Appelbaum and Grisso, 1995		X	X	X	X		X
Competency to stand trial							
Golding et al., 1984	X	X	X	X			X
Civil competence							
Schwartz and Barone, 1992	X	X	X	X			
Testamentary capacity							
Spar and Garb, 1992	X	X					

"quality of reasoning" indicated by weighing of risks and benefits. Absent from their scheme, however, is attention to the appreciation of the information to the subject's own situation. Another problem is their inclusion of a reasonableness of choice standard.

Wang and Ennis (1986) developed an elaborate "cognitive competency test" which includes subtests designed to assess memory, reading skill, verbal reasoning, and spatial orientation. The test is based on their multidimensional view of cognitive skills required for competence. While their assessment scheme addresses only global competence, they do recommend combining this assessment with a more focused assessment of "mental status." However, little mention is made of matching specific situational demands with specific skill tests.

Draper and Dawson (1990) present an example of another assessment scheme: a flowchart for determination of competency. The main decision nodes occur regarding understanding of illness and treatment alternatives. Of interest is the inclusion of a question about acknowledgement of illness but one problem with this assessment scheme, in addition to extensive reliance on understanding, is the reliance on rationality of choice for competence determination.

Fitten and Waite (1990) assessed understanding of various elements of the disclosure (the condition, the treatment, risks, benefits, and alternatives) and the "quality of patient's or subject's reasoning process" (p. 1718). These authors hint at a distinction between "bureaucratic" disclosure forms and forms geared toward patient understanding, but they do not expand upon the distinction. Prompting (cuing) helped their control group more than their hospitalized group. The hospitalized sample was impaired relative to controls on weighing of alternatives.

Like Wang and Ennis (1986), Freedman, Stuss, and Gordon (1991) identify attention, language, memory, and frontal lobe function as the "cognitive functions underlying competency" and base their suggestions for assessment on these four areas. Once these abilities are established, "then issues related to judgment and awareness must be critically evaluated" (p. 207). The result is a measure of global competence to the exclusion of situation-specific abilities.

A more recent system also relies upon understanding and little else. Janofsky, McCarthy, and Folstein (1992) base their assessment scheme on a quick measure of understanding of a disclosure. Comparison is made between their test instrument, the Hopkins Competency Assessment Tool (HCAT), and a forensic psychiatrist's assessment. Several criticisms have been made of HCAT. While it does assess understanding, other domains relevant to competence are unaddressed. Both Lavin (1992) and Sales (1992) note that reasoning or rational weighing of choices is ignored. Lavin also argues that relatively stable personal values are a required component of competence, one which HCAT does not measure. Englehart (1992) notes the lack of attention to the risk–benefit ratio of the choice in question, and Kaye (1992) notes that prognosis if no treatment is undertaken is not included in the HCAT disclosure vignette. Another problem of their assessment method is the potential for subjective error with their "gold standard" of clinician judgment. Thus, at best HCAT can be considered a measure of understanding only, and not a measure of a more global concept of competence.

Some of the work reviewed above suggests another crucial element to consider when assessing competence: context. Appelbaum, Mirkin, and Bateman (1981) observed that "The stress surrounding any hospitalization, whether psychiatric or medical, may contribute to a failure of rational modes of thought, as may the necessity for making critical decisions from a position of relative ignorance about the medical issues involved" (p. 1175). Empirical evidence supports this claim. According to Fitten and Waite (1990), the context of hospitalization impaired performance in general: in their sample of older adults, 28% of the hospitalized subjects had impaired performance on a vignette decision-making task despite no evidence of cognitive impairment on a standardized mental status exam or via clinical assessment (Fitten and Waite, 1990). Dellasega, Smyer, Frank, and Brown (1996) and Frank (1995) also found evidence of decision-making impairment despite relatively high mental status exam scores among their elderly hospitalized subjects. The specific causes of impairment (e.g. the subject's illness, medical interventions) are unknown, but these studies suggest that hospitalized older adults are one group "most vulnerable to decisional impairments" (Fitten & Waite, 1990).

Consideration of context in competence assessment is also crucial in long-term care settings. Increasingly the nursing home is recognized as a setting in which decisional capacity assessments are often required, and research suggests that three-quarters of nursing home residents exhibit some decisional capacity impairments (Goodwin, Smyer, & Lair,1995). Pruchno, Smyer, Rose, Hartman-Stein, and Henderson-Laribee (1995) discuss methods that are objective, reliable, and easily administered to assess decision-making ability of residents in nursing homes.

Appelbaum and Grisso (1995) have developed three separate instruments for the purposes of assessing competence to provide informed consent, or more specifically, medical treatment decision-making capacity. The Understanding of Treatment Disclosure (UTD) assesses capacity to understand relevant information. The Perception of Disorder (POD) assesses appreciation of relevant information for the individual's own situation. The Thinking Rationally About Treatment (TRAT) assesses the individual's ability to manipulate relevant information rationally. The TRAT represents an expansion of the quality of reasoning standard that is part of Stanley et al.'s (1984) scheme. Stanley and colleagues use comparison of risks and benefits as their indicator of quality of reasoning; the TRAT goes beyond that and includes other abilities as well: consequential thinking, complexity of thinking, and the ability to generate consequences for choices. The TRAT, POD, and UTD instruments provide a consistent method for assessment based on relevant legal criteria, but have not yet been normed for use with older adults.

7.06.5.2 Assessment of Other Types of Competence

Some researchers have recognized the need to match assessment to the specific competence ability under question (Grisso, 1994; Roth et al., 1977). As demonstrated above, the law increasingly recognizes that competence is not a global construct. Instead, competence may vary by content area within an individual. It is possible to find "islands of competent functioning" (Gutheil & Bursztajn, 1986) in an otherwise incompetent individual. Attention to the context of the assessment is therefore desirable.

Civil competence, testamentary capacity, and competency to stand trial are all distinct concepts from competence to consent to treatment, but important work has been done in assessment of each of these types, and that work is relevant to the discussion here. The assessment of both civil competence and competency to stand trial share elements with several approaches to assessing capacity to consent to treatment. The Community Competence Scale-Revised (CCS-R, Schwartz & Barone, 1992) was developed to assess civil competence, and the Interdisciplinary Fitness Interview (IFI, Golding, Roesch, & Schreiber, 1984) was developed to assess competency to stand trial. Both attempt to tie mental health issues to legal requirements by including assessment of psychological functioning. The CCS-R contains 17 subscales and the IFI contains 16, so while they clearly address global aspects of competence, the high degree of detail offers the potential for quite specific applications. Further, by attending to both psychological and legal issues, they represent an attempt to bridge the divide between Faden and Beauchamp's (1986) two senses of consent and competence.

Spar and Garb (1992) state that to assess competence one must determine global mental status, assess specific aspects of mental functioning relevant to the ability in question, determine implications of those abilities for the specific context, and finally, form a diagnostic impression. Although it was developed for the assessment of testamentary capacity rather than treatment, their assessment fits well with the four components discussed by Grisso (1994): diagnostic impression addresses the causal component, determining abilities relative to context addresses the interactive component, and the functional component is implied in the assessment of mental functioning. Given their goal of presenting assessment consonant with current legal and social systems, the judgmental component is implied.

Several problems exist in most 1990s assessment schemes. First, rarely does assessment address all of the specific domains relevant to competence, that is, causal processes and interactive components as well as functional abilities. Instead, as noted above, many systems are based on assessment of global competence. Individual-centered and contextually sensitive systems are rare. Second, few authors attend to the subjective components of their assessment schemes. As with definitions of competence, some assessment schemes allow societally determined standards of reasonableness or rationality to intrude. Third, criteria for success on an ability are often set casually rather than following formal investigation. The relative weight each ability should be given in an assessment is largely neglected. Fourth, there is a dearth of norms for older populations. Thus, when gauging the functioning of older people, it is difficult to assess their relative standing.

Increasingly, psychological and legal conceptualizations of competence are being tied together. Linking the two increases complexity, but conceptualizations of competence have been improved by this increased attention to the relationship between psychological and legal issues. Rigorous investigation of definitions, standards, and assessment methods will further refine and improve our understanding of competence.

Miller and Cugliari (1990) surveyed long-term care facilities in New York State regarding treatment policies and found that only 12% of responding facilities had written guidelines for the determination of decisional capacity in 1986. By 1988 that number grew to 48%. The content of those policies varied, but of interest is the trend toward increased attention to formalizing the assessment process through guidelines. The question, however, is what should be contained in those guidelines? Additional empirical investigation of the concept of competence is required before that question can be answered.

7.06.6 COMPETENCE IN ACTION: ADVANCE DIRECTIVES

In multiple contexts, from law courts to medical clinics, competence assessment is central to the protection of autonomy and fulfillment of society's obligation to protect individuals. Every day, competence of individuals—especially older adults—is brought into question, but in the early 1990s a new area emerged making decisional competence even more prominent. Because of advances in life-sustaining technology, and because of the increased cost of these technologies, social and governmental forces recognized the need for increased attention to decision making about life-sustaining technologies. Particular attention was focused on decision making in the event that an individual becomes incompetent, increasing concern for the proper assessment of competence. Because of their relevance to decision making by older adults, developments in end-of-life decision making are reviewed below. The Patient Self-determination Act (PSDA) is used as an example of a social context in which decision-making concerns are played out.

7.06.6.1 The Patient Self-determination Act

The PSDA became effective in December 1991, and requires that all institutional Medicare and Medicaid participants address the question of advance directives (ADs) with patients (Omnibus Budget Reconciliation Act, 1990). According to regulations published by the Health Care Financing Administrations (Medicare and Medicaid Programs, 1992), all competent individuals have the right to issue ADs. The capacity of an individual to create an AD is explicitly equated with the capacity of that individual to provide informed consent for medical treatments. However, the extent to which the two capacities may differ is unknown. One study directly compared AD and medical treatment decision-making capacity (Frank, 1995). While few quantitative differences emerged, the relationships of variables like cognitive status and verbal ability to the two types of decision making differed, suggesting that the decision types may be distinct. Given the significant consequences of end-of-life decisions, closer empirical attention to differences between capacities is necessary.

The need for instruments to assess decisional capacity is acute and growing (Fitten and Waite, 1990; Stanley, Stanley, Guido & Garvin, 1988; Kapp, 1992). The hospital is the focus of most serious medical interventions and thus hospitalized older adults are often called upon to make serious medical treatment decisions. The PSDA has drawn attention to an often neglected area of treatment decisions, those centered on life-and-death concerns. The mandates of that law (specifically the requirement to address AD issues with newly admitted hospital patients) increase the prominence of the hospital as the site for such life-and-death decisions for patients. Developments in the area of assisted suicide have focused additional attention on end-of-life decisions.

7.06.6.1.1 Knowledge and attitudes of the elderly about ADs

Zweibel and Cassel (1989) report criteria that older adults use in making hypothetical end-of-life treatment decisions. Prominent among them are the desire to avoid being a burden to family, the desire to avoid living with impaired cognitive function, and the desire to avoid pain.

According to self-report data, individual characteristics that most influence preferences regarding life-sustaining treatments of hospitalized elders are personal values, religion, and personal experience with illness (self or others) (Cohen-Mansfield, Droge, & Billig, 1992). Multiple studies have found that most patients want to discuss ADs (Emanuel, Barry, Stoeckle, Ettelson, & Emanuel, 1991; Gamble, McDonald, & Lichstein 1991; Lo, McLeod, & Saika, 1986; Shmerling, Bedell, Lilienfeld, & Delbanco, 1988; Smucker et al., 1993; Wolf et al., 1991).

The validity of an individual's preference regarding life-sustaining treatment is of concern for both ethical and legal reasons. One index of the validity of patients' preferences is the stability of those preferences over time. Several studies indicate high stability over time (cited in Wolf et al., 1991). However, the effect of several specific potential influences on preferences and their stability have been studied in detail, especially depression, prognosis information, and information framing.

(i) Depression

Because of concern about the potential for depression to invalidate decisions to avoid life-sustaining treatment, the relationship of depression to preference stability has been examined. In their examination of 43 older adults admitted to an inpatient psychiatric facility for major depression, Ganzini, Lee, Heintz, Bloom, and Fenn (1994) found an association between treatment for depression and preference for life-sustaining treatment: 26% of the subjects preferred more life-sustaining treatment following treatment for depression. However, these subjects were initially rated as more severely depressed than the rest of the sample. Among individuals with less severe depression, preferences remained relatively stable. In a separate study comparing depressed and nondepressed elderly patients, Lee and Ganzini (1994) found higher variability in stated preference over time among the depressed group. Of interest is their finding that their depressed subjects did not differ from control subjects in actual choices made (in either frequency or kind). A limitation of the Lee and Ganzini study is that it does not examine the extent to which change in preference is related to relevant legal standards for informed consent, like change in level of understanding of the information and/or change in ability to manipulate the information rationally. If the mechanism of action of depression on preferences is through these abilities, then assessment of the abilities, rather than of depression *per se*, is appropriate. The relationship between the abilities and level of depression must therefore be explored.

Additional studies are required to address the role of depression in preference stability, but the influence of depression on decisional capacity itself remains to be explored.

(ii) Prognosis information

As noted by Torian, Davidson, Fillit, Fulop, and Sell (1992), Do-Not-Resuscitate (DNR) orders indicating that in the event of a cardiac arrest, health providers should not attempt to resuscitate the patient, are unique among potential advance directives because of the necessity for quick response in the case of cardiac arrest, leaving no time for a decision change. They found that the majority of frail elderly on an inpatient geriatric medicine unit express a preference to have cardiopulmonary resuscitation (CPR) performed rather than forego it. However, patients in this study were not presented with prognosis information, another potential influence on patient preferences.

In an important experimental study of patient preferences for the DNR type of advance directive, Murphy et al. (1994) report that probability of survival does in fact influence patient preferences for CPR. They questioned ambulatory geriatric patients about desire for DNR orders in three different hypothetical situations: following an accident, in the event of an acute medical illness, and in the event of chronic illness. Over 40% of their sample expressed a desire for CPR to be performed following an accident or acute illness. Only 11% would desire CPR in the event of chronic illness. Next, subjects were asked their preferences for CPR following presentation of probabilities of survival to discharge following CPR for each of the three situations. Presentation of this information reduced by half the number of patients who would request CPR. These authors conclude that once presented with probability of survival information, most patients would choose not to undergo CPR.

Murphy et al. (1994) demonstrated that preference for CPR decreased with age: once the probability of survival was discussed, only a few subjects over age 85 would opt for CPR in any of the three hypothetical situations. Clearly, potential prognosis is a crucial factor to be considered in any advance directive decision, but this study leaves the influence of mode of information presentation unexplored.

(iii) Information framing

Evidence suggests that the manner in which information is presented may exert a strong influence on preference (Mazur & Merz, 1993; Redelmeier, Rozin, & Kahneman, 1993; Tymchuk, Ouslander, Rahbar, & Fitten, 1988). For example, the following two explanations present the same outcome: (i) 90 of 100 patients survive an operation and 34 are alive after five years; (ii) 10 of 100 patients die after surgery, and 66 die by the end of five years. Subjects express a preference for the procedure associated with the first version; the procedure associated with the second version is nonpreferred. Thus subject preference for a medical procedure is dependent upon the way in which outcome statistics are framed (Redelmeier et al., 1993).

Similarly, subjects prefer zero risk to any risk when deciding between two risk reduction dilemmas, regardless of the magnitude of risk reduction for the nonzero choice (reported in Redelmeier et al., 1993). Subjects are also more averse to loss than they are enthusiastic about gains. These effects highlight just some of the ways in which framing of information can influence subject choice. Any exploration of decisional capacity must therefore attend to manner of presentation.

7.06.6.1.2 Practical and ethical aspects of implementation of the PSDA

This subsection uses the PSDA as an example to review some of the concerns relevant to older adults' decision making, including timing of decision, standards for acceptance of decision, assessment of the validity of the decision, and coercion.

As required by the PSDA, patients must be approached at admission with information about ADs. As expressed by Wolf and colleagues (1991), "Implementation may result in drowning patients in written materials on admission, [and] insensitive and ill-timed inquiry into patients' preferences"; therefore "Concern ... persists about whether the time of admission or initial receipt of treatment is an appropriate moment to broach the topic of directives" (p. 1667).

Another potential problem with PSDA implementation relates to standards for acceptance of ADs. Some authors maintain that the strictness of the standard for accepting informed consent should be directly proportional to the seriousness of the consequences of the decision (Drane, 1985).

Drane (1985) strongly supports a contextual definition of competence. He outlines three levels of standards to be used based on the situation at hand. At the lowest level, decisional consequences are minimal, and awareness and assent are all that are required of the individual. With more serious decisions, understanding and expression of a choice based on medical outcomes is required. For the most stringent level, appreciation of the situation and rationality of the decision are required.

Roth et al. (1977) also outline a context-specific standard for competency tests, based on the risk–benefit ratio of treatment and whether the patient is accepting or refusing the treatment in question. The sliding scale notion has an important limitation, however: the degree of seriousness of the decision is determined by the assessor and not by the individual being assessed.

In the course of describing a treatment refusal scenario, Drane (1985) writes: "Objectively, the standard medical treatment is preferable to what she decides" (p.20). The preference is the author's. Elsewhere, he describes a voluntary psychiatric hospitalization scenario, in which the patient's consent to hospitalization is accepted as valid at a low threshold. A "higher degree of competence" will be required, however, if "more dangerous" treatment is required (p. 18). Drane's view is that there are treatments more serious than limiting one's own freedom via hospitalization. This is the author's opinion, but certainly different individuals may have different, but potentially equally valid, ranking systems for "evils" (Culver & Gert, 1982). Fitten and Waite (1990) also acknowledge the problem of assessor perspective, stating that the threshold for competence is influenced by the assessors' view of "normality" (p. 1720).

How should clinicians rate the seriousness of the decisions included in ADs? Should a lower standard of acceptance be applied to DNR orders than to withdrawal of nutrition and hydration requests? Is the "seriousness" hierarchy of medical interventions applicable to end-of-life issues?

Discussion of attitudes of older adults towards advance directives must also include reference to the role of families in medical decision making. Families are usually included in critical decisions by health care professionals as well as by the patient (Watts, 1992). In fact, Ely, Peters, Zweig, Elder, and Schneider (1992) demonstrated that clinicians will defer to the family, even in the presence of an advance directive document. Also, most state laws regarding surrogate decision making set up explicit hierarchies based on family relationship to the patient. The role of the family in decision making by older adults will be addressed further in the next section.

Another concern about PSDA implementation relates to a unique feature of ADs: one may decide not to decide, and instead designate a proxy decision maker. Alexander Capron has written that consent requires disclosure of information because information is "necessary to make meaningful the power to decide" (quoted in Freedman, 1975). The case of proxy designation in advance directives presents a special challenge to this interpretation of informed consent. By specifying another individual to make decisions for them, individuals may be engaging in "valid yet ignorant consent" (Freedman, 1975). In addition, AD decisions may be invalid due to subtle impairments in judgment or reasoning.

A related ethical concern raised by PSDA is the threat of involuntary rationing through coercion (Callahan, 1988; Jecker, 1988). Assessment of the extent to which an older adult's decision about ADs is truly informed and voluntary is therefore an important means of avoiding coercion.

7.06.7 OTHER ISSUES

7.06.7.1 Other Considerations for Decision Making

7.06.7.1.1 The nature of preferences

Any complete consideration of medical decision making requires attention to the nature of preferences and choices. What exactly is a choice? What is the definition of a preference? Available research suggests that static preferences are a myth (Slovic, 1995). Instead, a more useful conceptualization is that of preferences that are constructed "on the spot by an adaptive decision maker" (Slovic, 1995, p. 369). As Slovic notes, "decision making is a highly contingent form of information processing, sensitive to task complexity, time pressure, response mode, framing, reference points, and numerous other contextual factors" (p. 369). Consideration of the role of the family (discussed further below) represents one step towards contextual sensitivity to the decision-making process. Other factors need to be addressed, including the formation of personal values and their relationship to medical decisions and the influence of information from different sources on values and decision outcomes.

"Negotiated consent" has been suggested as a means of supporting patient autonomy (Moody, 1988); a closely related concept is that of "participative decision making" in which patient and clinician share responsibility for each phase of the decision-making process (Ballard-Reisch, 1990). However, if one accepts the premise that individuals actually construct decisions based on a variety of factors, including information framing, information presentation, and method of response elicitation (Slovic, 1995), then negotiated consent does not necessarily bring us closer to the goal of autonomous, valid consent. The ideal of legally valid informed consent requires a full comprehension of the disclosed information by the individual. Negotiated consent puts the individual at risk of making less than legally informed and valid choices based on a variety of factors, including the individual's relationship to others involved in the decision, and the manner in which information is portrayed.

In practice, decisions are not purely rational (Appelbaum, et al. 1987). Explorations of ways to improve the informed consent process must acknowledge the multiple sources of choice construction. As discussed earlier, depression, prognosis information, and information framing are among the factors that might influence decisions. More importantly, the potential for improving the nature of informed consent must be explored. Simple remedial measures should be tested. For example, expanding explanation of alternatives and treatment choices during a disclosure may improve understanding of information (Grisso & Appelbaum, 1995), and may ultimately improve the quality of the choice rendered.

7.06.7.1.2 The role of the family

As noted above, some older adults defer consent to participate until they can consult with a family member (Gueldner & Hanner, 1989) and many studies document the tendency for older adults to rely on family members in medical treatment decision situations (High, 1993; Kapp, 1991; Zweibel & Cassel, 1989). One potential reason for this preference may be related to a general lack of familiarity among older adults with technological advances. Reasons have not been explored in depth, but the ability of older adults to consider the issues involved in end-of-life decisions needs to be measured.

Because of evidence of the preference of some older adults for family involvement, some commentators suggest that society's emphasis on individual autonomy is misplaced in the case of older adults; instead, courts should adopt a "rebuttable presumption in favor of family surrogates" (High, 1991). High argues that by favoring autonomy over family involvement, the current system denies the role of caring concern on the part of the family in decision-making, and it underestimates the role of values shared by the family unit.

Kapp (1989) points out additional problems with an individual autonomy focus for older adults. The current view simply transfers decisional authority from the institution to the patient, with the danger of condoning neglect when older adults do not exercise their autonomy sufficiently. Instead, he argues, autonomy is best blended with beneficence, with "negotiated sharing" the result. In this way the institution's obligations towards the patient are not dismissed in the name of autonomy. Kapp makes the additional point that autonomy "is the capacity for self-determination" and the individual is free to choose to exercise autonomy or not.

Of interest is that many states in the USA have a "family consent" statute in which authority for medical treatment decisions is designated to family members, in a specific order based on relationship to the patients, in the event that the patient becomes unable to make or communicate his or her own choices. The law in most states therefore recognizes the prime role of family in health care decisions for incapacitated individuals.

In practice, evidence suggests that many older adults make decisions in collaboration with others, particularly with family members (Kapp, 1991). Among the reasons why older adults may choose to share decision making is to minimize family burden (Kapp, 1991), and concern among older adults about family burden has been documented (e.g., Zweibel and Cassel, 1989). Thus, assessment approaches require sensitivity to the role of the family for a full understanding of decision making by older adults.

7.06.7.2 Directions for Future Research

Assessment of decisional capacity requires solid theoretical formulations of decisional capacity as well as construction of valid and reliable assessment instruments. In the late 1990s, most of the theoretical formulations about decisional capacity stem from the legal requirements for informed consent. Instrument development requires that theoretical formulations be translated into measurable psychological constructs. This translation has proven difficult, however, given the differences between legal traditions and psychological traditions.

Requirements of legal informed consent stipulate that treatment choices and alternatives be discussed, along with risks and benefits of treatments. The doctrine of informed consent was developed through the legal tradition, in the absence of empirical testing. If certain elements of the informed consent disclosure are more difficult than other elements (in terms of subject understanding), then the legal goal of valid, informed consent may not be being met. If portions of the informed consent disclosure are truly more difficult than other portions for subjects to understand, then remedial measures are indicated. Either the doctrine of informed consent must be reconsidered, or special attention must be given to the communication of certain elements of the disclosure. Rather than relying on a set of criteria for informed consent, perhaps health care professionals should consider a more focused question and ask “informed consent for what?”

For informed consent for research, a sliding scale has been suggested (Levine, 1995). It may be the case that such a sliding scale is appropriate for medical treatment decisions as well. For example, if individuals can understand the symptoms of their disorder and the risks and benefits of a low-risk treatment, they can be considered competent to decide whether to accept or reject that treatment. However, if understanding is intact for symptoms, risks, and benefits, but impaired for other choices or alternatives, then a limited decisional autonomy may be appropriate. The positive effect of corrected feedback on understanding of informed consent information has been documented (Taub, Kline, & Baker, 1981). The extent to which simple feedback could improve performance on these measures should be addressed.

Application of additional measurement methods could enhance understanding of decisional capacity. For example, item response theory and factor analysis could contribute to identification of the distinct latent traits measured by each instrument. The relevance of those traits to legal requirements for competence could then be quantified. These methods could also reduce respondent burden of many instruments. Improved conceptualization and measurement awaits application of advanced methodologies to this area.

In addition to making consent procedures more situation-specific, researchers should aim to make the procedures more subject-specific as well. Identifying specific predictors of performance for groups of subjects (hospitalized adults, cognitively impaired patients, etc.) represents one strategy for matching the subject and the task. Another strategy involves identification of individual-level differences, such as differences in verbal ability or level of depressive symptoms. Quantifying the effects of these differences on the informed consent process could lead to improvements in the match of individual to context.

When considering “older adults” it is necessary to remain aware of heterogeneities within the population. As Murphy et al. (1994) found, adults over the age of 85 were distinct from other older adults in terms of reaction to a CPR scenario (see Section 7.06.6 for a synopsis). Different age groups may have a different constellation of responses to decision-making tasks. Further research is needed to identify the range of responses across a broader age range.

Many studies explore decisional capacity at a single time point. However, a single-time study is inadequate for full characterization of decisional capacity for several reasons. First, many studies document the susceptibility of hospitalized older adults to transient shifts in cognitive functioning (e.g., Francis, Martin, & Kapoor, 1990). Thus the role of time in obtaining informed consent is particularly important for this population. Second, a single-time study provides no information about the developmental nature of the phenomenon under study. Both short-term changes (including those resulting from training or other intervention) and long-term changes should be explored. There may be important differences between an individual's decision making before and after a health crisis; a prospective study could address this question. A longitudinal examination of the same subjects could provide insight into another important aspect of decision-making: the relationship between the stability of patient preferences and the validity of the patient's choices. There is a growing literature on the stability of patient preference over time (e.g., Emanuel et al., 1991; Everhart and Pearlman, 1990), but few studies address both AD decision and medical treatment decision stability.

A body of research exists about adolescent treatment decision making (e.g., Ambuel & Rappaport, 1992; Ginsburg et al., 1995; Lewis, 1987; Mann, Harmoni, & Power, 1989; Scott, Repucci, & Woolard, 1995). Much could be gained theoretically and empirically by linking work on the development of decisional capacity with work on the expression of decisional capacity in later life. Also, some of the questions about the role of age and health status in decision making should be addressed.

The goal of obtaining legally and ethically valid informed consent for treatment is a worthy one, but many commentators agree that practices in the late 1990s fall short of this goal (Culver & Gert, 1982; Mazur, 1988; Rodwin, 1989; Taub, Baker, & Sturr, 1986; Tymchuk & Ouslander, 1990). Improving our understanding of the many issues involved in decision-making by older adults will improve the decision-making process. The aging of our society assures that these issues will have increasing personal and public policy relevance.

7.07.1 THE AIMS OF NEUROPSYCHOLOGICAL ASSESSMENT

In the early days of clinical neuropsychology, most neuropsychological assessment was aimed at answering questions concerning differential diagnosis and lesion location. With the rapid advances in brain imaging technology the importance of this aim has diminished; the focus of assessment has moved to identifying the cognitive and behavioral consequences of cerebral dysfunction whether this be for rehabilitative or medico-legal purposes. However, the neuropsychologist continues to play a valuable role in these former areas, most notably in the diagnosis of dementing illnesses. In addition, although most neuropsychologists work in acute neurological/neurosurgical services or rehabilitation settings, most also take direct referrals from general medical and psychiatric services. As a result of this they are often the first to establish evidence for the presence of a neurological disorder.

Medico-legal assessments constitute a significant part of many neuropsychologists' workloads. Areas of particular relevance to the elderly in which a neuropsychological opinion is sought include issues of guardianship (e.g., is a client competent enough to manage their own financial affairs?) and fitness to hold a driving license. Other areas include personal injury litigation, fitness to plead in criminal cases (i.e., could a client with known or suspected neuropsychological deficits follow a legal argument against her/him and have an appreciation of its import), and evaluation of pleas of diminished responsibility (i.e., did pre-existing neuropsychological deficits impair a client's responsibility for her/his actions?).

In broad terms, neuropsychological assessment is aimed at answering the following questions:

(i) Which components of the cognitive system are dysfunctional, how severe is this dysfunction, and also, just as importantly, which components have been spared?

(ii) To what extent has there been change in mood, comportment, and personality; to what extent are these likely to be a direct effect of neurological damage as opposed to a psychological reaction to any injury or illness?

(iii) What are the implications of any changes in cognition, mood, and comportment for a client's every day functioning now and in the foreseeable future?

(iv) Based on the pattern of cognitive strengths and weaknesses and changes in mood and comportment, what practical advice can be given regarding the design of any formal rehabilitation and what advice can be given to the client and significant others to help them adjust to any deficits?

These questions are answered by integrating information gained from the medical notes, an interview with the client (and whenever possible a relative or close acquaintance), and the qualitative and quantitative findings from formal neuropsychological testing.

7.07.2 SOME SPECIFIC CONSIDERATIONS IN NEUROPSYCHOLOGICAL ASSESSMENT OF THE ELDERLY

There is a strong relationship between sensory deficits and cognitive function in elderly populations. For example, Lindenberger and Baltes (1994) conducted structural equation modeling of the relationship between age, cognitive test performance, and sensory functioning in an elderly sample (age range 70–103) and found that visual and auditory acuity accounted for 49% of the total and 93% of the age-related variance in cognitive performance. They evaluated a number of causal hypotheses to explain this relationship and concluded that it arose because both cognitive performance and acuity were indicators of the underlying physiological integrity of the aging brain. However, an additional possibility not considered by Lindenberger and Baltes is that sensory deficits impose an additional central processing load, resulting in poorer performance on cognitive tasks. Consistent with this possibility, Rabbit (1990) has reported that elderly subjects with 35–50 db hearing loss could repeat aloud flawlessly words read out to them but showed poor recall relative to age and IQ-matched controls with good hearing. In contrast, they had no such problem when the words were presented visually. This effect can be modeled in young subjects with good hearing when they have to process words heard through white noise. Rabbitt (1968) found that, under these conditions, the words were repeated successfully but recall was poor. It would appear, then, that the extra effort expended on making out the material places demands on processing resources which would otherwise be free for rehearsal or elaborative encoding, etc. This has far-reaching implications for the interpretation of neuropsychological test results in the elderly as evidence that clients are able to successfully to make out the stimulus materials does not rule out the possibility that their sensory deficits, rather than a higher level problem, has impaired their performance.

The presence of sensory loss should also be borne in mind when attempting to evaluate if there is dispositional change resulting from a central organic process. For example, hearing loss can lead to withdrawal from previous social activities because of frustration and the impatience of others.

Test fatigue can be an issue with the elderly and requires avoiding long test sessions. The neuropsychologist should also be sensitive to the possibility of effects arising from the order of test administration when examining test profiles. Clinicians experienced in working with individuals with dementia, particularly those in the early stages, will also be aware of their ability to "lift their game" for short periods sometimes to the frustration of their relatives who have sought an appointment because of concerns over cognitive deterioration.

As the result of more elderly people taking an increased interest in their health and the risks associated with aging, the neuropsychologist can play an important role in establishing objective evidence of adequate performance, thereby providing reassurance to clients.

Prior to 1990, there was a lack of adequate normative data on neuropsychological tests for the elderly. However, as governments have digested the implications of the change in the age structure of their populations, resources have been allocated to large-scale studies such as the Australian Longitudinal Study of Ageing (e.g., Bryan, Luszcz, & Crawford, 1997), the Cambridge Ageing Project (see Huppert, 1994), the Mayo Older Americans Normative Study (e.g., Ivnik et al., 1992), and the Canadian Study of Health and Aging (e.g., Tuokko & Woodward, 1996) among others. As a result, it will soon be possible to have better norms for the elderly than for other age groups.

The conventional approach to norming of tests is to obtain a sample which has been screened carefully to exclude potential participants with any medical conditions which may have a detrimental effect on cognitive performance. The case for an alternative approach has been well made by Huppert and colleagues. For example, Huppert (1994) has argued that "Rather than excluding individuals with risk factors which might affect performance, normalisation samples should be based on unselected population samples and the effects of these risk factors should be examined" (pp. 315–316). These two approaches are best seen as complimentary rather than competitors. Comparison of an individual's performance with conventional norms, or norms based on regression scores derived from demographic variables (i.e., age, education, current or former occupation, etc.), can address the issue of whether there is evidence of acquired impairment in a particular functional domain. The latter approach, presumably using multiple regression equations, can then potentially inform the clinician as to whether such impairment is likely to be unusual for someone with this particular combination of factors in their medical history. It should be noted, however, that this latter approach would be complex and would require very large samples.

7.07.3 THE NEUROPSYCHOLOGICAL INTERVIEW

Conducting a neuropsychological interview demands considerable empathy, tact, and intellectual effort. In many cases, the client will have multiple cognitive and physical disabilities and organically induced changes in mood and personality; they will also be attempting to cope with the often massive interpersonal and economic upheaval arising from their illness or injury. Added to this is the fact that a neuropsychological assessment can be anxiety provoking because of potential threats to self-esteem or because of its medico-legal ramifications; accordingly some clients can exhibit more concern at the prospect of such an assessment than over the lengthy and sometimes painful and bewildering physical investigations they may have to undergo.

As in all clinical interviewing, time must be spent establishing rapport and clarifying the nature and purpose of the investigation. General, open-ended, and nonthreatening questions should be employed, followed by a request for the client to describe any problems they have been experiencing in their everyday life. The client's description of these everyday problems constitutes a principal source for the generation and refinement of clinical hypotheses which will be tested in the course of the examination. Such descriptions and follow-up questions are also crucial in establishing the degree of insight the client has into the nature and severity of their deficits. Lack of insight is a major barrier to effective intervention and a client's successful adjustment. A client may exhibit a cheery disregard in the face of severe deficits coupled with grossly unrealistic expectations concerning a return to a former occupation or lifestyle; in other cases there may be a disproportionate concern with a relatively minor cognitive or physical problem when other deficits have much more serious implications.

Often, the most useful clinical information from the interview is gained by asking clients about their short-, medium-, and long-term goals and how they intend to achieve them. Answers to such questions are relevant to assessing drive, mood, planning ability, and level of insight. Inquiries about how they spend a typical day can also be employed to address these issues which have implications for the approach that should be adopted in any rehabilitation/remediation attempts. As Brooks (1989) states in this latter context, "the examiner is attempting to estimate whether the patient is a passive receptor of disability or an active fighter struggling to achieve a better outcome" (p. 66).

The neuropsychologist has a large agenda to cover in the interview and often will be under time pressure; this necessitates a structured, systematic inquiry. However, most formal neuropsychological tests also provide a structure for the client; the examiner sets out the concrete aims and rules, and largely controls the pace and order of the items administered (see the section on assessment of executive deficits for further discussion and exceptions to this). It is, therefore, important that enough of the interview is minimally structured to determine the extent to which the client initiates and organizes the discussion of topics.

A detailed educational history is important in building a picture of a client's premorbid abilities. The history should include years of schooling (with a check on whether any of these were repeat years), the nature of any tertiary education and any further study (evening classes, day release, etc.), and formal qualifications and grades achieved. The possibility that health, economic, social, or attitudinal factors may have prevented a client achieving their full educational and occupational potential should be carefully explored.

The client should be asked to describe the nature of their previous and/or current occupation with a detailed breakdown of the duties and functions performed. The nature of their work and responsibilities provides additional clues to general premorbid level of functioning but also an indication of specific premorbid cognitive skills that are likely to have been strongly developed/highly practiced. The clinician should inquire if there have been any recent changes in living circumstances, and if relevant, the work environment (i.e., introduction of new technology, reorganization of duties) as such changes can often be the catalyst which exposes problems in an individual who had previously been coping despite diminished cognitive resources.

Lezak (1995) sets out a number of fundamental questions which must be addressed prior to formal testing; these include: does the client understand the reason for referral and do they have specific questions of their own they want answered? Do they understand the uses to which the information gained from the examination may be put and who will and will not have access to it? (of particular importance in medico-legal contexts); do they know how and when feedback will be provided? Finally, do they appreciate that the assessment will largely be concerned with cognitive functioning (misperceptions abound) and are they aware of the general nature of the tests to be employed? In individuals with severe deficits the answers to these questions cannot be fully in the affirmative and it is therefore important that their relatives or guardians are briefed.

7.07.4 BASIC PSYCHOMETRIC ISSUES

7.07.4.1 The Rationale of Deficit Measurement in Clinical Practice

Attempting to detect and quantify cognitive deficits in the individual case is problematic because of the wide variability in cognitive abilities within the general population. Scores on neuropsychological measures which are average or even above average can still represent a significant impairment for an individual of high premorbid ability (and have serious implications for return to a previous lifestyle or occupation). Similarly, test scores which fall well below the mean do not necessarily reflect an acquired impairment for an individual whose premorbid resources were modest. Because of this, normative comparison standards are of limited utility in neuropsychological assessment and must be supplemented by individual comparison standards when assessing acquired deficits (Crawford, 1992; Lezak, 1983; Walsh, 1991). Ideally, this individual comparison standard can be obtained from psychological test scores obtained in the premorbid period. However, this is rarely a viable option; the amount of routine psychological testing conducted varies greatly between countries so that many individuals may have had no prior formal testing. Even where such test results exist they are often difficult or impossible to obtain, the content of the tests may have limited relevance, or they may have been administered so long ago that they are of questionable value. Because of these difficulties clinicians normally have to settle for an individual comparison standard which is based on a client's current performance. The explicit rationale here is that (i) cognitive ability measures are almost invariably positively correlated, therefore performance on one measure allows some level of prediction of performance on another, and (ii) some abilities will be preserved, or relatively so, following most neurological injuries or illnesses. Thus, the areas in which a client has performed best are used as the standards (i.e., estimates of premorbid ability) against which to compare performance on other measures. Large discrepancies between measures are taken as indicators of the presence and severity of acquired impairment (Lezak, 1991).

7.07.4.2 Converting Scores to a Common Measurement Scale

In constructing a neuropsychological profile of a client's strengths and weaknesses, most clinicians use instruments drawn from diverse sources. These instruments will differ from each other in the measurement scale used to express test scores; for some instruments no formal scaling will have been developed so that clinicians will be working from the means and standard deviations (SDs) of the raw score from normative samples. The process of assimilating the information from these tests is eased greatly if the scores are all converted to a common scale of measurement.

Converting all scores to percentiles has the important advantage that percentiles are comprehended easily by other health workers. However, because such a conversion involves an area transformation (i.e., the difference between a percentile score of 10 and 20 does not reflect the same underlying raw score difference as that between 40 and 50), they are not ideally suited to the rapid and accurate assimilation of information from a client's profile; percentiles are also inappropriate for use with many inferential statistical methods. Z scores do not suffer from these problems but have the disadvantage of including negative values and decimal places which can cause problems in communication.

One option is to convert all scores to have a mean of 100 and SD of 15 (McKinlay, 1992) as tests commonly forming a part of the neuropsychologist's armamentarium are already expressed on this scale, that is, IQs and factor score indices on the Wechsler Adult Intelligence Scale-Revised (WAIS-R; Wechsler, 1981), memory indices from the Wechsler Memory Scale-Revised (WMS-R; Wechsler, 1987), and estimates of general premorbid ability such as the National Adult Reading Test (NART; Nelson & Willison, 1991). The most common alternative is to use *T* scores (mean 50; SD = 10); the meaning of such scores are easy to communicate and are free of the conceptual baggage associated with deviation IQs.

Regardless of which method is used, the clinician must be constantly aware that the validity of any inferences regarding relative strengths and weaknesses is heavily dependent on the degree of equivalence of the normative samples for the test results compared. Although the quality of normative data for neuropsychological tests has improved markedly since the 1980s, there are still tests used in practice which are standardized on small samples of convenience, the representativeness of which are largely unknown. Thus, discrepancies in an individual's profile may in some cases be more a reflection of differences between normative samples than differences in the individual's relative level of functioning in the domains covered by the tests.

7.07.4.3 Reliability

Adequate reliability is a fundamental requirement for any instrument used in neuropsychology regardless of purpose (Franzen, 1989). However, when the concern is with assessing the cognitive status of an individual its importance is magnified, particularly as the demands of clinical practice are such that decisions, must be commonly made based on information from single administrations of each instrument.

Information on test reliability is used to quantify the degree of confidence that can be placed in test scores, for example, when comparing an individual's scores with appropriate normative data or assessing whether discrepancies between scores on different tests represent genuine differences in the functioning of the underlying components of the cognitive system as opposed to simply reflecting measurement error in the tests employed. In the latter case, that is, where evidence for a differential deficit is being evaluated, it is important to consider the extent to which the tests are matched for reliability; an apparent deficit in function A with relative sparing of function B may simply reflect the fact that the measure of function B is less reliable. This point was well made in a classic paper by Chapman and Chapman (1973) in which the performance of a schizophrenic sample on two parallel reasoning tests was examined. By manipulating the number of test items the schizophrenic sample was made to appear to have a large differential deficit on one or other of the tests.

Particular care should be taken in comparing test scores when one of the measures is not a simple score but a difference or ratio score. Such scores are used quite commonly in neuropsychological assessment; for example, in the assessment of implicit memory functioning a priming score may be derived from the difference between completion of word fragments (e.g., c–pe– / carpet) from a list that has been primed in an earlier study phase and an unprimed list (performance on the unprimed list essentially controls for individual differences in verbal ability). This priming score will have poor reliability because the measurement error associated with the two lists is additive. For example, if both lists had reliabilities of 0.75 and an intercorrelation of 0.6, the formula for the reliability of a difference score (e.g., see Crocker & Algina, 1986) reveals that the reliability of this priming score would be only 0.37. This compares unfavorably with the reliability of most explicit memory tests and raises the danger that the clinician may conclude that an individual has impaired explicit memory coupled with preserved implicit memory when the pattern may simply be an artifact of differences in reliability.

7.07.4.4 Reliable vs. Abnormal Differences

The distinction between the reliability and the abnormality of differences between test scores is an important one in clinical neuropsychology. A difference between scores normally would be considered reliable if it exceeded the 95% confidence interval for the difference, that is, a difference of this magnitude is unlikely to have arisen from measurement error in the instruments. Establishing if a difference is reliable is only the first step in neuropsychological profile analysis. There is considerable intraindividual variability in cognitive abilities in the general elderly population such that reliable (i.e., statistically significant) differences between tests of these different abilities are common. In evaluating the probability that a discrepancy reflects acquired impairment, it is important to consider the abnormality or rarity of the difference, that is, what percentage of the general (i.e., unimpaired) elderly population would be expected to exhibit a difference of this magnitude?

Base rate data, which permits the clinician to assess the abnormality of test score discrepancies, is available for some neuropsychological measures. When such data are not available, a simple formula can be used to estimate the abnormality of any discrepancy from the correlation between the two tests of interest (see Payne & Jones, 1957). It is also possible to assess the abnormality of the discrepancy between a single test and a client's mean scores on a series of measures (Silverstein, 1984).

To highlight the distinction between the reliability and abnormality of a difference take the example of a discrepancy between the General Memory and Attention/Concentration indices of the WMS-R. A discrepancy of 17 points would be necessary for a reliable difference ($p < 0.05$). Based on the average correlation between these two indices in the WMS-R standardization sample ($r = 0.51$), approximately 25% of the general population would be expected to exhibit a discrepancy of this magnitude; to be abnormal (operationally defined for the present purpose as discrepancy which would occur in less than 5% of the general population), a 29-point discrepancy would be required.

The importance of evaluating the abnormality of discrepancies through base rate data or correlational techniques cannot be overstressed. Most clinical neuropsychologists have not had the opportunity to administer neuropsychological measures to significant numbers of individuals drawn from the general elderly population. It is possible, therefore, to form a distorted impression of the degree of intrasubject variability found in unimpaired individuals. The impression is that the degree of normal variability may be underestimated leading to a danger of overinterference when working with clinical populations. For example, Matarazzo, Daniel, Prifitera, and Herman (1988) have reported that in the WAIS-R standardization sample, a sample presumed to be free of neurological or psychiatric disorder, the mean difference between an individual's highest and lowest WAIS-R subtest score was 6.7. For this difference (i.e., the subtest range to be abnormal it would have to exceed 11 Scaled score points. As subtests have an SD of 3, it can be seen that a subtest range of around 3 SDs is not unusual in individuals without acquired impairments. These considerations are just as relevant when profile analysis is carried out with more specific neuropsychological instruments. The WMS-R and WAIS-R are used here as examples simply because of the availability and quality of the relevant data.

7.07.4.5 Monitoring Change

There are many situations in which the neuropsychologist needs to measure potential changes in cognitive functioning in the elderly. Common examples would be to determine whether cognitive decline is occurring in an individual in whom a degenerative neurological process is suspected, or to determine the extent of recovery of function following a stroke or traumatic brain injury. In both these cases, neuropsychological assessment will provide useful information to assist clients, relatives, and other health professionals to plan for the future. Monitoring the cognitive effects of surgical, pharmacological, or cognitive interventions in the individual case is also an important role for the neuropsychologist. Although the aim here is most commonly to determine if there has been any improvement, the possibility of detrimental effects can also be an issue. For example, many drugs can potentially impair cognitive functioning, particularly in the elderly. Anticholinergic agents provide a good example as they are widely used in the treatment of various conditions and yet can have serious negative effects on cognition, particularly memory (Crawford, Besson, & Ebmeier, 1990).

In assessing the effectiveness of a rehabilitation effort it is often possible to obtain multiple repeated measures of an individual's performance before, during, and after intervention. A number of inferential statistical techniques can be used in this situation because there are multiple data points for the different phases (see Barlow & Hersen, 1984 for a general treatment of single-case designs). However, in general clinical practice the neuropsychologist often must come to conclusions about change from only a single retesting. This situation will also arise in rehabilitation settings; although multiple measures may have been obtained on the training task(s), the issue of the generalizability of any improvement is often addressed by comparing single before-and-after scores on related, but separate tests.

Monitoring change on the basis of a single retesting is a formidable task except in cases where the level of change has been dramatic. It is rendered more formidable by the fact that many of the standard instruments used in clinical neuropsychology (e.g., the WMS-R) do not have parallel versions. The clinician must therefore differentiate changes resulting from systematic practice effects and random measurement error from change reflecting genuine improvement or deterioration. Among other complications are the fact that (i) the magnitude of practice effects vary with the nature of the task (e.g., the Performance subtests of the WAIS-R show larger practice effects than their Verbal counterparts), (ii) the length of time that has elapsed between test and retest will influence the magnitude of effects, and (iii) a diminution of practice effects is to be expected in neurological populations given the high prevalence of memory and learning deficits, but the expected diminution is difficult to estimate for individuals.

One approach to dealing with many of these considerable interpretive problems is to gather information from test–retest studies on the relevant neuropsychological tests. Provided that such studies report the test–retest correlations, means, and SDs, regression equations can be constructed to predict performance on retest from scores at initial testing. The predicted scores are then compared with the retest scores actually obtained by the client to assess whether the observed gain or decline significantly exceeds that expected (see Knight & Shelton, 1983; McSweeny, Naugle, Chelune, & Lüders, 1993). The utility of this approach is determined by the extent and nature of retest studies available for a particular test. For example, the test–retest scores on memory tasks for an elderly client with suspected dementia could be compared with estimated retest scores derived from a healthy, elderly sample retested after a similar period to gauge how atypical any decline may be. For some questions test–retest data from a clinical sample may be used. For example, a stroke patient's scores on measures of attention or speed of processing could be compared with estimated retest scores from a stroke sample if the clinician suspects that the extent of recovery is atypical.

7.07.5 APPROACHES TO ASSESSMENT IN CLINICAL NEUROPSYCHOLOGY

Approaches to the assessment process can be characterized as falling on a continuum between what has been referred to as the "fixed, big battery" approach and a flexible, hypothesis-testing approach (Brooks, 1989; Walsh, 1991). In the former, a large comprehensive battery is routinely administered to all clients. This approach is most common in the USA and is exemplified by the Halstead–Reitan battery which consists of a large number of specific neuropsychological measures, for example, tests of tactual performance, sensory extinction, finger tapping, categorization, language functioning, etc., which are often supplemented with a full-length WAIS or WAIS-R and personality inventories (see Reitan, 1986).

In the latter approach, measures are selected to test clinical hypotheses derived from the neuropsychological literature on a client's known or suspected disorder and from information gained from the interview. The process is a dynamic one; the results of preliminary testing are used to test or modify existing hypotheses and generate new ones. As a simple example, screening measures may detect problems with the organization of visual material which are consistent with spatial and/or planning deficits; follow-up measures can then be administered to evaluate these three competing possibilities.

Proponents of the flexible approach acknowledge that there is a potential danger of failing to detect a client's difficulties in some cognitive domains if the clinician focuses too rapidly on testing inappropriate hypotheses (Miller, 1992). However, they argue that the fixed, big battery approach may represent an inefficient use of resources and is simply not an option in some hard-pressed services (Brooks, 1989; Walsh, 1991). Further, because of the time taken to complete an assessment, many of the measures may be administered by psychology assistants rather than fully accredited clinicians. It has been argued that important clinical information may therefore be missed or misinterpreted (Brooks, 1989). In the fixed, battery approach all clients and normative groups are administered the same tests, therefore services employing this approach accumulate substantial data on their measures. Such databases are tremendous clinical assets. However, the very existence of this database, and the resources expended to obtain it, may promote a reluctance to substitute existing tests with newer measures designed to reflect developments in neuropsychological knowledge.

Approaches to assessment can also be characterized by the emphasis placed on qualitative vs. quantitative evidence. The extreme quantitative pole of this dimension is characterized by a strict statistical/actuarial methodology in which comparison of a client's test scores against various cut-offs is the principal focus. At the other extreme, tests are used to reveal qualitative features of a client's behavior, the emphasis being on how a task is approached rather than on any empirical analysis of the test scores obtained. In the service of this end there may be major deviations from standardized test instructions, thus precluding statistical analysis in any case. Although there is no fundamental reason why this dimension should not be orthogonal to the fixed/flexible dimension, in practice they have tended to be correlated. The fixed, battery approach arose from researchers working in the actuarial tradition and the sheer number of measures administered almost demands the employment of actuarial indices to assist in the assimilation of the information obtained.

A strict quantitative methodology could be employed with the flexible hypothesis-testing approach. Indeed, the term hypothesis-testing might be seen as implying this and indeed influential figures in the development of this approach devoted considerable attention to quantification (e.g., Shapiro, 1973). However, many clinical proponents of this approach have tended to emphasize qualitative analysis that is, hypotheses may be expressed and tested in qualitative as well as quantitative terms (Walsh, 1991). It should be stressed that very few clinical neuropsychologists are at the extreme ends of this qualitative/quantitative dimension; qualitative observations are verified with quantitative instruments whenever possible whilst recognizing that much important information is not easily amenable to such verification.

7.07.6 SCREENING TESTS FOR MENTAL STATUS

This section will briefly review screening tests for mental status. All these Scales include questions covering basic orientation for time and place but differ in the extent to which they address other competencies. Among the most common Scales are the Mini Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975), the Mattis Dementia Rating Scale (MDRS; Mattis, 1976), and the cognitive section (CAMCOG) of the Cambridge Mental Disorders of the Elderly Examination (CAMDEX; Roth et al., 1986). These instruments produce a global score which summarizes a patient's cognitive competence. They are brief and easy to administer and provide sufficient information for epidemiological studies, or as an index of severity of decline. They cannot be viewed as exhaustive diagnostic instruments.

The MMSE (Folstein et al., 1975) is probably the most frequently used screening Scale and is often used as part of a larger battery for a comprehensive assessment of dementia. It is a very brief and easily administered instrument and takes about 5–10 minutes in total. It tests orientation, information, and visuoconstructive abilities; total scores can range between 0 and 30. In their original study, Folstein et al. reported a high test–retest reliability of 0.83 when retesting was conducted by a different examiner, and 0.89 when the same examiner was used. High test–retest reliability, ranging from 0.8 to 0.95, has been confirmed by later studies (Anthony, Le Resche, Niaz, Van Korff, & Folstein, 1982; Dick et al., 1984). An effect of age on MMSE scores has been reported by several studies (Magni, Binetti, Bianchetti, Rozzini, & Trabucchi, 1996; Pi, Olive, & Esteban, 1994; Tombaugh & McIntyre, 1992). Furthermore, caution is required when interpreting scores obtained from poorly educated individuals. Level of education has been shown consistently to have an effect on MMSE score (Kittner et al., 1986; Kukull et al., 1994; Uhlmann & Larson, 1991).

A useful instrument for the evaluation of the mental status is the Mattis Dementia Rating Scale (MDRS) (Mattis, 1976). This Scale can take about 30–45 minutes to administer, but since items are ordered in descending order of difficulty passes on early items can shorten the time required because of discontinuation rules. The MDRS tests orientation, attention, initiation and perseveration, visuoconstructive abilities, conceptualization, and memory. Split-half reliability for this Scale is high (0.90) (Gardner, Oliver-Munoz, Fisher, & Empting, 1981). Norms are available (Montgomery, 1982); however, according to Spreen and Strauss (1991) the normative sample cannot be considered representative of the elderly population as it contained a disproportionate number of high socioeconomic status (SES), highly educated participants.

As noted, the CAMDEX (Roth et al., 1986) includes a cognitive section (CAMCOG). This Scale contains the items of the MMSE with the addition of some additional coverage of perception, memory, and abstract thinking. A study (Huppert et al., submitted) has examined the psychometric properties of the CAMCOG; the test–retest reliability of the Scale as a whole was very high (0.86), as was its internal consistency (coefficients ranged from 0.82 to 0.89). A study carried out in a group of 222 elderly people reported that CAMCOG scores are affected by age, sociocultural factors, and hearing and visual deficits (Blessed, Black, Butler, & Kay, 1991). The cognitive subScale of the Alzheimer's Disease Assessment Scale (Rosen, Mohs, & Davis, 1984) is used increasingly widely in clinical trials in DAT because of its proven sensitivity to the effects of cholinesterase inhibitors and other drugs (Schneider, 1996). It takes around an hour to administer and includes tests of word recall, orientation, naming, spoken language and comprehension, and constructional praxis.

7.07.7 MEASURES OF CURRENT INTELLECTUAL ABILITY

7.07.7.1 Use of the WAIS-R With the Elderly

The WAIS-R (Wechsler, 1981) continued to be used widely in neuropsychological assessment of all individuals of all ages. Lezak (1988a), for example, describes the Wechsler as, "the workhorse of neuropsychological assessment" and identifies it as "the single most utilized component of the neuropsychological repertory" (p. 38). A number of points should be made about the use of the WAIS-R with the elderly. First, as will be discussed later, many clinicians base their analysis of WAIS-R performance on a client's subtest profile. It is important that age-graded Scaled scores are used in this process rather than the standard Scaled scores which are not corrected for age (Lezak, 1995). Failure to use these former scores can produce a totally misleading picture of individuals' strengths and weaknesses relative to their peers; (see Crawford, 1992 p. 27). Second, as aging is associated with reduced visual acuity, it is regrettable that the stimulus materials for some of the subtests (most notably Picture Completion and Picture Arrangement) are unnecessarily small and the artwork poor.

The most obvious problem in using the WAIS-R with the elderly is that the original norms only cover those up to age 74 years. For clients over this age two sets of independently collected norms are available (Ivnik et al., 1992; Ryan, Paolo, & Brungardt, 1990). The Mayo norms were established on a sample of 512 healthy individuals from Rochester and surrounding areas in the US and covers up to age 97 years. However, many of the total subject pool were under age 74 years and were used to examine the comparability of the MAYO norms with the existing WAIS-R norms. Thus, the norms for those over age 74 years were based on a subsample of 222. The sample was relatively highly educated and had an underrepresentation of ethnic minorities. Two features of these norms are potentially appealing. First the norms were established using the method of overlapping midpoint age ranges described by Pauker (1988); this takes maximum advantage of the data available and, because it permits more age bands to be formed, lessens the sometimes substantial apparent improvement in scores that can occur when an individual moves from one age band to the next. As an aside, it is worth noting that, using the existing WAIS-R norms and any spreadsheet package, it is possible to go one step further and derive continuous norms for those aged under 74 years (see Zachary & Gorsuch, 1985). Second, age corrections are carried out at the subtest level rather than when converting the sum of Scaled scores to IQs. This is the same approach used for the Wechsler children's Scales; why it was not adopted for the adult Scales remains a mystery.

Ryan et al's. (1990) norms were established for two age groups, 75–79 ($n=60$) and 80 and above ($n=70$). Although this sample was somewhat smaller than the Mayo sample, it was recruited to be broadly representative of the US elderly population in terms of those demographic variables that were considered to be most pertinent to cognitive tests. Paolo and Ryan (1995) discuss the pros and cons of both samples in detail. They also provided an example subtest profile for a case aged 75 years (i.e., just outside the standard WAIS-R norms) and compared the results obtained by both sets of elderly norms and by scoring the case as if he were 74 years using the original norms. The original and Ryan norms showed much greater evidence of convergence; the Mayo norms indicated significant deficits on some Performance subtests which were not present in the other two profiles. An additional advantage of the Ryan norms is that base rate data on subtest scatter and other aspects of performance are available (e.g., Ryan & Paolo, 1992).

7.07.7.2 Analysis of Subtest Profiles

Analysis of WAIS-R performance can be based on the IQs, the subtests or scores derived from factor analysis. Authorities on the Wechsler have divided opinions on the usefulness of the summary IQs. Matarazzo and Herman (1985), for example, have suggested that the discrepancy between Verbal and Performance IQs is the best validated Wechsler index of cerebral dysfunction, whereas Lezak (1995) is dismissive of its importance. Many clinicians primarily base their interpretation of the WAIS-R on the pattern of strengths and weaknesses in a client's subtest profile (e.g., Lezak 1995; Walsh, 1991). Lezak (1988b), for example, notes that IQs can obscure clinically important strengths and weaknesses and suggests that "although the traditional scoring scheme for the Wechsler exemplifies the IQ problem, these tests also show us a way out of the problem by providing a profile of (subtest) scores" (p. 359).

A starting position in conducting such a profile analysis is to assess whether any observed subtest differences are reliable (i.e., statistically significant) as opposed to simply reflecting measurement error. The only assistance for this process provided in the WAIS-R manual appears in Table 13 (Wechsler, 1981). This table provides the critical values required for significance when comparing any subtest with any other. It is appropriate to use these critical values if and only if the clinician has made an *a priori* decision to examine the difference between only one pair of subtests out of the 55 potential comparisons that could be made. However, in practice, clinicians will want to compare more than one pair; indeed, when the client's history and behavior at interview provide insufficient grounds for forming clinical hypotheses, such comparisons will be *post hoc*. In effect, all possible comparisons are made in this situation even though the clinician will focus attention on the subtest comparisons which yielded the largest discrepancies.

The principal problem with Wechsler's approach is that it does not introduce any correction for the inflation of the Type I error rate that occurs when multiple comparisons are conducted (Crawford, 1992; Silverstein, 1982). Any attempt to overcome this problem inevitably involves striking a balance between controlling the Type I error rate while retaining reasonable power to reject the null hypothesis of no subtest differences. For example, an unsatisfactory solution would be to produce a modified table in which a Bonferroni correction was applied to derive new critical values reflecting the fact that 55 comparisons were involved. Although such an approach would control for inflation of the Type I error rate, it would result in very low power to detect subtest differences, that is, the Type II error rate (i.e., the rate of false negatives) would be unacceptably high.

Knight and Godfrey (1984) and Silverstein (1982) independently suggested a method which achieves a useful compromise between the need to minimize both Type I and Type II errors; instead of potentially comparing all subtests with each other, each subtest is compared with a client's mean subtest score. In the case of a full-length WAIS-R this reduces the number of comparisons to 11 so that, when the Bonferroni correction is applied to maintain the Type I error rate at the specified level, the loss of power to detect subtest differences is much less acute; 11 appears in the denominator rather than 55. Both authors provided a table which recorded the size of discrepancy between each subtest and an individual's mean subtest scores required for varying levels of statistical significance. This approach, when combined with equivalent tables on the abnormality of any subtest differences (see below), provides a rapid and straightforward means of analyzing a client's profile of strengths and weaknesses and therefore provides information which can be integrated usefully with other quantitative and qualitative information available to the clinician.

Crawford (1997) presented a modified table which corrects a minor error common to both of the original tables. Further tables are provided for use with any of nine short-forms of the WAIS-R, including those specifically developed for neuropsychological purposes (e.g., Reynolds, Willson, & Clark, 1983; Walsh, 1991) and those in which the selection of subtests was guided by their suitability for use with the elderly and other groups in which reduced visual acuity can be a problem (e.g., Britton & Savage, 1966; Crawford, Allan, & Jack, 1992a).

If subtest differences are found to be reliable, it is often appropriate to determine if they are also abnormal, that is, to establish how rarely differences of the magnitude observed in an individual's profile occur in the general population (see Section 7.07.4.4). Many healthy individuals have reliable strengths and weaknesses in their subtest, thus reliable differences do not imply the presence of acquired impairment. Silverstein (1984) provided a table to assess the abnormality of subtest differences. As was the case for the reliability of subtest differences, this table is used to compare each subtest with an individual's mean subtest score. Crawford, Allan, McGeorge, and Kelly (1997) adopted the same method to prepare a set of abnormality tables for use with any of the nine WAIS-R short-forms referred to earlier.

The above methods allow clinicians to test hypotheses based on clinical experience or the research literature on a client's known or suspected neurological disorder. However, the methods themselves make no *a priori* assumptions about the nature of an individual's subtest pattern. In contrast, there have also been attempts in the past to identify fixed, specific subtest patterns for differential diagnostic purposes. Most of these attempts naively aimed to identify "organicity" and hence were based on a unitary concept of brain damage which is totally discredited. Not surprisingly, empirical studies of these profiles, such as Wechsler's "Hold–Don't Hold" pattern, have been consistently disappointing (e.g., Christensen & MacKinnon, 1992; Savage, Britton, Bolton, & Hall, 1973).

A more rational and interesting attempt to identify specific subtest patterns was conducted by Fuld (1984). This approach arose from evidence implicating cholinergic dysfunction in the cognitive deficits seen in dementia of the Alzheimer type (DAT) (e.g., Perry et al., 1978; see Crawford et al., 1990 for a review). Fuld (1984) examined Drachman and Leavitt's (1974) data on the effects of scopolamine on the WAIS performance of healthy adults and reported that the age-graded subtest profile could be typified by the formula $A > B$; $B > C$, $C \leqslant D$, $A > D$ where A is the mean of Information and Vocabulary, B of Similarities and Digit Span, C of Digit Symbol and Block Design, and D is Object Assembly. Fuld reported that around a half of patients with DAT exhibited this profile, whereas it was observed in less than 7% of controls and patients with multi-infarct dementia (MID). These results provoked much interest (see Massman & Bigler, 1993 for a review). Subsequent studies have reported rates of occurrence in DAT ranging from a high of 57% (Brinkman & Braun, 1984) to a low of 7% (Logsdon, Teri, Williams, Vitiello, & Prinz, 1989). Most subsequent data on the specificity of the profile indicated that it occurred with low frequency in the healthy elderly and in neurological disorders other than DAT. However, reasonably high rates of occurrence have been reported in depression (16%) and schizophrenia (15%). A particularly disappointing set of results was reported in the previously mentioned study by Logsdon et al. (1989) in which the 7% rate of occurrence in DAT was exactly equivalent to the rates in the healthy elderly and depressed patients. Gfeller & Rankin (1991) have also reported that the profile was exhibited by 12% of cases of multi-infarct dementia, a figure which is little different from the rate found in their DAT sample (15%).

With knowledge on the extent of intraindividual variability in subtest scores (e.g., Matarazzo et al., 1988), it should not be surprising that the profile has low sensitivity for DAT. For example, it would not be uncommon for individuals to have premorbid Block Design or Digit Symbol scores which were well over one SD higher than their average subtest score; similarly, it would not be uncommon for individuals to have Information or Vocabulary scores which were substantially below their average subtest score. Thus, although these sets of subtests may be differentially affected by the onset of DAT, a massive effect would be required to reverse the premorbid pattern; accordingly, these differential effects often would be obscured in the individual case. In conclusion, the Fuld profile has little to recommend its use in clinical practice. However, it is still of some theoretical interest as scopolamine-treated healthy subjects and DAT cases are apparently the only groups studied to date in which the profile is exhibited in their respective means. This provides some support for the cholinergic hypothesis in DAT. However, it should be noted that there has been no attempt to replicate the original report on the effects of scopolamine. It would also be important to demonstrate that the profile has pharmacological specificity, that is, that a similar profile would not be observed following administration of a benzodiazepine or some other centrally active agent.

7.07.7.3 WAIS-R Factor Scores

An alternative to the analysis of both IQs and subtest discrepancies is to examine scores obtained from factor analysis of the WAIS-R (Atkinson, 1991; Canavan, Dunn, & McMillan, 1986; Crawford, Allan, Stephen, Parker, & Besson, 1989a; Kaufman, 1990). Although this suggestion has a long history (Maxwell, 1960), factor scores have not been employed widely in clinical practice or research. Factor analyses of the WAIS and WAIS-R commonly have extracted three factors: a verbal (V) factor on which Information, Vocabulary, Comprehension, and Similarities have high loadings; a perceptual–organization (PO) factor defined by high loadings from Block Design and Object Assembly (other Performance subtests have more modest loadings); and a third factor termed attention/concentration (A/C) or freedom-from-distractibility consisting of Arithmetic, Digit Span, and often Digit Symbol (Crawford et al., 1989a; Leckliter, Matarazzo, & Silverstein; 1986). The arguments in favor of using factor scores when interpreting WAIS-R performance are many and compelling. First, the IQs do not have optimal construct validity, the subtests were allocated to a Verbal and Performance Scale on intuitive grounds. Second, the factor structure of the WAIS-R appears to be very robust in that it is consistently extracted from samples from countries outwith the USA. Most crucially, it emerges when the WAIS-R scores of clinical samples are factor analyzed (e.g., Atkinson, Cyr, Doxey, & Vigna, 1989). Third, the reliabilities of factor scores are much higher than those of the individual subtests from which they are formed. Fourth, although authorities on the Wechsler have laid stress on the analysis of subtest scatter, the WAIS-R could be viewed as primarily providing broad indicators of current functioning against which more specific neuropsychological measures are compared. Again, the superior construct validity of the factorially derived composites suggest they are better suited to provide these broad intraindividual comparison standards than the IQs.

Crawford, Johnson, Mychalkiw, and Moore (in press-a) have examined the clinical utility of IQs, indices of subtest scatter, and factor scores in discriminating between healthy ($n = 356$) and head-injured samples ($n = 233$). The scatter indices employed were the Profile Variability Index (McLean, Reynolds, & Kaufman, 1990), which simply records the variance of an individual's subtest scores, and The Mahalanobis Distance Index (Burgess, 1991); this latter index factors in the correlation between subtests (therefore, a discrepancy involving a subtest which has a relatively low average correlation with the other subtests is given less weight than a discrepancy involving a subtest with a high correlation). Factor scores were significantly better than both the IQ Scales and the scatter indices at discriminating between healthy and impaired performance; the scatter indices essentially performed at chance levels. The extent to which these findings will generalize to neurological conditions more directly associated with the elderly (e.g., DAT, stroke, etc.) remains to be determined.

The lack of a rapid method of factor scoring the WAIS-R, combined with the absence of data with which to assess the reliability and abnormality of discrepancies between factors, acted as barriers to the effective use of factor scores in clinical practice. Both these limitations have simultaneously been rectified in a very useful paper by Atkinson (1991).

7.07.8 SPECIFIC METHODS FOR THE ESTIMATION OF PREMORBID ABILITY

The National Adult Reading Test (NART) (Nelson & Willison, 1991) is the test most widely used to estimate premorbid ability. The NART is a single word, oral reading test consisting of 50 items. All the words are irregular, that is, they violate grapheme–phoneme correspondence rules (e.g., chord). Because the words are irregular, intelligent guess work should not provide the correct pronunciation, therefore the test taps previous word knowledge; as the test only requires the reading of single words, clients do not have to analyze a complex stimulus and it is argued that the test therefore makes minimal demands on current cognitive capacity (Nelson & O'Connell, 1978). Development of the NART arose from the clinical observation that oral reading is commonly preserved in dementia (whereas reading for meaning is commonly impaired). However, the test is used to estimate premorbid ability in a wide range of conditions.

To qualify for use as a measure of premorbid ability, a test must fulfill three criteria (Crawford; 1992; O'Carroll, 1995). First, as with any psychological test, it must possess adequate reliability. The NART has high split-half reliability/internal consistency, test–retest reliability, and inter-rater reliability (Crawford, 1992). Second, it must have high criterion validity. The NART is normally used to provide an estimate of general premorbid IQ against which current performance on the WAIS-R is compared. Thus, to meet the second requirement, the NART must be capable of predicting a substantial proportion of IQ variance. There has been some confusion in the literature on how to examine this aspect of putative measures of premorbid ability (e.g., Klesges, Wilkening, & Golden, 1981), so it is worth noting that it must necessarily be studied using unimpaired rather than clinical samples. In a clinical sample, NART performance and performance on the criterion (e.g., the WAIS-R) will commonly become dissociated, indeed it is the presence of such a dissociation (i.e., a large discrepancy between estimated premorbid ability and current ability in favor of the former) that is used to infer impairment. In most studies using the WAIS or WAIS-R as the criterion variable the NART predicted well over 50% of IQ variance. For example, in one study the NART predicted 66% of WAIS IQ variance in a sample of 151 healthy subjects (Crawford, 1992).

The final criterion for a putative measure of premorbid ability is that test performance be resistant to neurological or psychiatric disorder. NART performance appears to be largely resistant to the effects of many neurological and psychiatric disorder, for example, depression, acute schizophrenia alcoholic dementia, closed head injury, and Parkinson's disease (Crawford, 1992; O'Caroll, 1995) and compares favorably with previously suggested alternative measures of premorbid ability such as the Vocabulary subtest of the WAIS or WAIS-R (e.g., Crawford et al., 1988). Mixed findings have been found in samples with probable DAT. O'Carroll, Baike, and Whittick (1987) readministered the NART to a sample of dementia cases after one year and found no change in performance despite a significant decline on measures of dementia severity. Crawford et al. (1988) found that the NART performance of DAT cases did not differ significantly from matched controls despite the presence of severe deficits on other cognitive measures and the presence of marked morphological and blood flow abnormalities on brain imaging. Stebbins, Wilson, Gilley, Bernard, and Fox (1988), in contrast, found that NART performance was impaired significantly in DAT cases classified as moderate or severe, although impairment was not in evidence in mild cases. Subsequent studies have continued to produce conflicting results in DAT (e.g., Patterson, Graham, & Hodges, 1994; Sharpe & O'Carroll, 1991) but it is becoming increasingly clear that NART performance can be impaired substantially in many cases of moderate to severe dementia. Any findings of impaired NART performance poses a threat to the validity of this approach. However, the practical implications of impaired performance in cases of severe neurological disorder are not as serious as they may appear; in such cases the presence of deficits is unfortunately only too obvious, thereby largely obviating the need for the NART or a similar instrument to assist in its detection and quantification.

Most research on the NART's ability to estimate premorbid ability has used scores on IQ tests as the criterion variable. Although this is in keeping with the notion of obtaining an estimate of general level of premorbid functioning, the NART also has the potential to provide estimates of premorbid functioning for other WAIS-R indices and for more specific neuropsychological tests. For example, Crawford, Moore, and Cameron (1992c) built a regression equation which can be used to estimate premorbid performance on the FAS verbal fluency test (see Section 7.07.13). Similarly Crawford, Obonsawin, and Allan (in press-b) have provided an equation which uses NART and age to estimate premorbid scores on the Paced Auditory Serial Addition Test (PASAT; Gronwall, 1977).

Schlosser and Ivison (1989) derived a regression equation which incorporated age and NART scores to estimate performance on the Wechsler Memory Scale (WMS). They reported that the discrepancy between current WMS performance and estimated premorbid performance was a highly successful index for the detection and quantification of memory dysfunction in DAT. O'Carroll et al. (1994) extended this work by comparing a group of DAT patients, a group of depressed patients, and a group of healthy controls on the discrepancy between NART-estimated premorbid intellectual ability and current mnemonic ability as assessed using the various indices of the WMS-R. While large mean differences were demonstrated between groups, the degree of overlap between the DAT and depressed group was large, leading them to conclude that none of the NART/WMS-R discrepancy quotients were significantly discriminating between depression and DAT to be useful in clinical practice.

A proposed modification to the NART is the Cambridge Contextual Reading Test (CCRT; Beardsall & Huppert, 1994). As its name suggests, the NART words are embedded in sentences to provide context for the examinee. Baddeley, Emslie, and Nimmo-Smith (1993) proposed another alternative reading test which they termed the Spot The Word Test (STW). STW is a lexical decision task in which the examinee has to identify the legitimate words from a series word/pseudoword pairs (e.g., stamen/floxid). Both of these new tests have considerable potential as alternatives to the NART. However, their use is mainly limited to research applications as regression equations have yet to be developed to provide estimates of premorbid ability for individuals and there is insufficient evidence on their resistance to impairment.

An entirely different approach to the estimation of premorbid ability uses demographic variables (e.g., years of education, occupational classification) as predictors. This has the advantage that the estimates it provides are entirely independent of current level of functioning (care should, however, be taken to assess whether prodromal difficulties could have led to a client's failing to achieve their educational or occupational potential). As evidence of impaired NART performance in various clinical conditions accumulates, the demographic approach may be a useful alternative method in cases where use of the NART would be inappropriate. However, the obvious disadvantage of the demographic approach is its modest criterion validity. Where WAIS or WAIS-R scores have been used as the criterion variable, regression equations based solely on demographic variables account for only 30–54% of the variance (Barona, Reynolds, & Chastain, 1984; Crawford & Allan, 1997; Crawford et al., 1989b; Wilson et al., 1978). This compares unfavorably with the NART and its variants (Crawford, 1992; O'Carroll, 1995).

7.07.9 AGING AND MEMORY

7.07.9.1 Introduction to Aging and Memory

It is a well-established phenomenon that as humans age, memory complaints increase. These subjective complaints are reflected in objective measurements of memory test performance. For example, Davis and Bernstein (1992) examined verbal memory performance, as assessed by the Auditory Verbal Learning Test (AVLT) in a sample of 474 healthy individuals ranging from those in their twenties to those in their eighties; a steady decrease in performance was observed with increasing age in those over 30 years. Free recall performance often appears to be more detrimentally affected by the aging process than recognition, although other memory processes do appear to be sensitive to age effects, for example, priming skill learning and classical conditioning (see Binks, 1989 and Schonfield, 1980 for reviews).

Shimamura (1994) proposed that age-related effects on memory may be associated with regional brain changes, that is, that problems of attention, working memory, word finding, and source memory may be related to aging effects in frontal lobe functioning, whereas problems with new learning may be related to medial temporal lobe dysfunction. Superimposed on these changes, Shimamura (1994) argued that general changes in neuronal efficiency may pervade all neural systems as a consequence of age (e.g., reduced blood flow, inability to prevent damage from oxidation, and poor metabolic uptake). It is proposed that these metabolic changes account for the pervasive finding of cognitive slowing in older individuals. It can be imagined easily how these specific age-related memory effects may act synergistically with nonspecific slowing to result in impaired performance. Evidence has shown that differing brain regions undergo differing degrees of neuronal loss with age. Many areas, such as striate-cortex and parietal cortex, do not lose an appreciable number of neurons during life. However, 15–20% of the neurons in the neo-striatum and frontal cortex are lost between young adulthood and old age (Squire, 1987). Similarly, approximately 5% of hippocampal neurons are lost per decade, so that at the age of 80 years; approximately 20–30% of hippocampal pyramidal cells will have been lost (Squire (1987). It is tempting, therefore, to link the neuronal cell loss in frontal and hippocampal regions to frontal and temporal memory systems which Shimamura (1994) has implicated in the aging process.

7.07.9.2 Age-associated Memory Impairment

Crook et al. (1986) proposed the concept of age-associated memory impairment (AAMI). The following criteria were developed:

(i) at least 50 years of age;

(ii) gradual onset of complaints of memory loss in everyday activities;

(iii) memory test performance one standard deviation below the mean of young adults on standardized tests of recent memory with adequate normative data;

(iv) adequate intellectual function (e.g., Scaled score of at least nine on WAIS-R vocabulary);

(v) absence of dementia (i.e., Mini-Mental Status Examination score of 24 or above); and

(vi) exclusion criteria, delirium, neurological disorder, cerebrovascular pathology, head injury, etc.

However, it is clear that a vast number of elderly people would meet these criteria, particularly the reference to scoring one standard deviation below memory test scores for young adults; indeed by definition over 16% of young adults would meet this criterion. This led to the proposed diagnostic category being severely criticized (e.g., O'Brien & Levy, 1992). Partly as a consequence of this type of criticism, AAMI was not included in the *Diagnostic and Statistical Manual of Mental Disorders* (*4th ed., DSM-IV*) of the American Psychiatric Association. Some skeptics felt that the condition may have been invented in order to legitimize pharmaceutical treatment of this new disorder. However, it is clear that aging is associated with significant impairment of memory functioning and more needs to be known about this naturally occurring phenomenon rather than labeling it as a categorical disorder. Caine (1992) has proposed that instead of the term AAMI, age-related cognitive decline (ARCD) should be discussed and researched and this has been included in *DSM-IV* (code 780.9).

7.07.9.3 Does Memory Functioning in Dementia Represent Accelerated Aging?

In many studies, the finding that memory after a delay is poorer in the elderly than in young subjects has usually been attributed to an acquisition deficit rather than to faster rate of forgetting. For many years, a controversy has raged over whether dementia (particularly of the Alzheimer type) represents accelerated aging effects or whether it represents a quite separate clinical entity (Huppert, 1994). In an important study, Huppert and Kopelman (1989) found that normal aging produces a mild acquisition deficit as well as a significant increase in forgetting rate, and the rapid rate of forgetting in the elderly cannot be attributed simply to differences in the initial level of acquisition. In a comparison of normal aging with dementia, normal aging produced a mild acquisition deficit and a slight increase in the rate of forgetting, whereas dementia superimposes a severe acquisition defect but no further effect on forgetting rate (Huppert & Kopelman, 1989). In their study, Greene, Baddely, and Hodges (1996) employed the Doors and People test (Baddeley, Emslie, & Nimmo-Smith, 1994; see below) in a comparison of early DAT patients vs. elderly controls. They concluded that the episodic memory deficit in DAT is general in nature and primarily reflects impaired learning rather than accelerated forgetting or disrupted retrieval. Thus, memory functioning in dementia appears to be qualitatively different from that observed in "normal" aging.

7.07.9.4 Commonly Used Memory Tests: Implications for use with Elderly Subjects

In the following sections several commonly used clinical memory measures will be outlined briefly and evaluated, with a particular emphasis on the appropriateness of their use with the elderly. For further details, the interested reader is referred to Lezak (1995) and Spreen and Strauss (1991). Unfortunately, pressure of space precludes coverage of all but a few of the most widely used instruments.

7.07.9.4.1 The Auditory Verbal Learning Test

The auditory verbal learning test (AVLT; Rey, 1964) is one of the most widely used word learning tests in clinical research and practice. Five presentations of a 15-word list are given, each followed by attempted recall. This is followed by a second 15-word list (list B), followed by recall of list A, and delayed recall and recognition are also tested. A key feature of the AVLT (and its successor, the California Verbal Learning Test) is that it affords the opportunity to measure rate of learning, as opposed to recall of a single stimulus, or series of stimuli. An equivalent form of AVLT has been provided by Crawford, Stewart, and Moore (1989c). Because of the rather abstract nature of the test, that is, 15 unconnected words and repetition over five trials, this can be a rather stressful measure for an elderly individual of failing cognitive abilities. The initial normative data that was referred to widely was rather limited (Lezak, 1983). However, the situation has improved, with excellent norms for the elderly provided by Geffen, Moar, O'Hanlon, Clark, and Geffen (1990), Ivnik et al. (1992), and Tuokko and Woodward (1996). The normative data on this test has also been reviewed by D'Elia, Boone, and Mitrushimo (1995). For a detailed review of the AVLT, see Peaker and Stewart (1989).

7.07.9.4.2 The California Verbal Learning Test

In an attempt to expand upon the assessment of learning and retrieval strategies, the California Verbal Learning Test (CVLT) evolved from the AVLT and was developed to provide an instrument "reflecting the multifactorial ways in which examinees learn, or fail to learn, verbal material. The CVLT's assessment of learning strategies, processes, and errors is designed for use in both clinical and research practice" (Delis, Kramer, Kaplan, & Ober, 1987). A variety of memory measures are obtainable from this measure including short- and long-term free recall and recognition, serial learning curves, learning strategy (i.e., semantic vs. serial clustering), etc. The CVLT also has the added advantage of presenting the stimuli in an everyday, relatively nonthreatening manner, that is, learning two shopping lists. The reliability data for the principal measures appear to be adequate although some of the scores which are derived from them have poor reliability. The normative database consists of 273 neurologically intact individuals, 104 males, 169 females, with a mean age of 58.9 (15.4) years. This mean age for controls is considerably higher than that normally employed for psychometric test development. However, the control subjects were recruited from several research projects and the authors state "in order to make the best use of the data while giving due regard to the varying number of cases at each age and sex, smoothed age curves were fitted to the raw data using multiple regression" (Delis et al., 1987, p. 35). This curve-fitting procedure for normative data has been criticized (see Elwood, 1991).

7.07.9.4.3 The Wechsler Memory Scale-Revised

The WMS-R (Wechsler, 1987) is generally considered to be a considerable improvement on its predecessor, the WMS. The WMS-R includes new subtests such as figural memory, visual paired associates, and visual memory span. As Mayes and Warburg (1990) comment, "the revised WMS therefore appears (potentially) to be considerably more satisfactory in a number of respects than its older brother—particularly in respect of normative data, information of standardization, validity and reliability, scoring criteria (especially logical memory), range of memory functions sampled and provision for clinical interpretation of test rests. This has been achieved at the cost of increased administration time, particularly if the Delayed Recall is tested, abandonment of provision of an equivalent alternate form, and increased cost of the test." For elderly subjects, however, the Delayed Recall Test requires an attempt to reach a criterion on both verbal and visual paired associates. This can lead to repeated experience of failure over six trials which can provoke distress in elderly individuals. In addition, the scoring of the tapping forwards and backwards subtest leads to considerable anxiety on the part of many psychologists as they find it an extremely difficult subtest to score. However, preliminary data on the inter-rater reliability of this subtest appears to be satisfactory (O'Carroll & Badenoch, 1994).

The normative sample consists of 316 subjects in six age groups, selected to be representative of the US population in terms of race, geographic region, education, and IQ. Elwood (1991) points out that the normative sample of 316 "seems hardly adequate for the standardization sample, given the broad age range of its target population. In relative terms, comparison between the WMS-R sample and the 2000 subjects used for the WAIS-R is striking" (p. 185). It is important to note that the WMS-R standardization sample systematically excluded subjects in the age range of 45–54 years using interpolated values in their place.

Given that the WMS-R is one of the most widely used memory tests, it would be expected that the normative sample would be representative of the general population. However, Huppert (1994) has pointed out that examiners were instructed to screen potential examinees for a list of several medical factors which may affect cognitive performance and has suggested that, not only were these criteria poorly specified, they almost certainly excluded a high percentage of normal nondemented older individuals. As she states, "this has serious consequences for the use of these norms in assessing whether or not an individual's memory performance is below that expected for their age. The effect will be to over-estimate the number of elderly people with clinically significant memory impairment" (p. 315). A further brief discussion of this issue can be found in Section 7.07.2.

7.07.9.4.4 The Rivermead Behavioural Memory Test

The Rivermead Behavioural Memory Test (RBMT) was designed specifically to try to detect impairment of everyday memory function by providing test items that resembled activities in everyday life, for example, remembering to deliver a message, remembering to retrieve a personal belonging after an interval, etc. The RBMT has the advantage of having four matched parallel versions, thus allowing for repeated assessment to determine the effects of disease progression and/or clinical intervention. An additional important advantage of the RBMT is the careful work the authors have undertaken in order to ensure the measure's validity. They assessed validity in three ways: (i) by demonstrating a high correlation between the RBMT and other standard memory tests; (ii) by demonstrating a high correlation between RBMT scores and subjective ratings of memory impairment; and (iii) most importantly, by demonstrating a high correlation between RBMT score and observer ratings of memory lapses (Wilson, Cockburn, Baddeley, & Hiorns 1989). Such a rigorous approach to demonstrating the ecological validity of a memory measure is both unusual and welcome.

In general, the RBMT is well tolerated by elderly individuals on account of its "everyday feel" and the fact that it consists of a number of brief, relatively nonthreatening subtests. The initial normative data were provided from 118 subjects aged 16–69 years. However, a supplement to the manual provides details of elderly healthy subject's performance and is, therefore, a welcome addition to the clinical neuropsychologist's armamentarium for the assessment of memory in the elderly adult. Cockburn and Smith (1989) recruited 119 people aged between 70 and 94 years, with a mean age of 80.5 years. In order to provide as random a sample as possible, every fourth name of people born in or before 1917 was taken separately from anyone from the age/sex register of a five-doctor general practice that covered both urban and rural areas. Such a detailed attempt to recruit a truly "normative" elderly sample is welcome. Furthermore, the authors determined that age and general intellectual ability were significant correlates of Rivermead performance. Accordingly, they developed useful tables for determining abnormal memory scores in relation to age and estimated premorbid intellectual level. This additional work renders the RBMT one of the best memory measures for use in an elderly sample. Furthermore, the nonthreatening nature of the stimulus materials makes it more user-friendly for an elderly sample than many of its competitors. A limitation of the RBMT is that it may be rather insensitive to mild impairments of memory. Following on from this, ceiling effects may be encountered in mildly impaired patients, making any positive effects of intervention difficult to demonstrate.

7.07.9.4.5 The Rey Complex Figure Test

This test has been used widely (Rey, 1964), particularly because of the dearth of adequate visuospatial memory tests. A complicated figure is presented and the subject is requested to copy it. The original and copy are then removed and the subject is asked to draw the figure again from memory, after varying delay intervals. As Mayes and Warburg (1990) point out there have been many variants on administration and scoring criteria; and the available norms, particularly for elderly samples, have been rather limited. Spreen and Strauss (1991), however, provide normative data from the age ranges 60–85 years. While this is a welcome addition, the numbers in each respective age band are again limited. For example, in the 70+ age range, the sample size is $n=10$. This obviously makes clinical interpretation somewhat difficult.

7.07.9.4.6 The Recognition Memory Test

The recognition memory test (RMT) is a widely used instrument, particularly in amnesia research (Warrington, 1984). It consists of two subtests, recognition memory for 50 words and recognition memories for 50 faces. Following presentation of the words and faces, the testee is required to perform an immediate two-choice recognition task and is generally considered to be less stressful and anxiety provoking than many other memory measures. The normative data consists of 310 control in-patients without cerebral disease, aged 18–70 years. As Nelson (1990) points out in a review of the RMT, "This test can only be used with subjects up to the age of 70 because of the unknown effects of normal aging on the test scores past this age."

7.07.9.4.7 The Doors and People Test

The Doors and People Test was devised in order to provide comparable measures of visual and verbal memory that test both recall and recognition, that does not provide floor or ceiling effects and includes both learning and forgetting measures (Baddeley et al., 1994). The test comprises four sections: a doors test, where single doors have to be recognized against three competing distracters; a shapes test, where diagrams have to be reproduced from memory; a names test, which is a verbal recognition test; and finally, the peoples test, where the subject is required to learn an association between a series of photographs and names. Normative data from 238 subjects is provided, in five age bands (16–31, 32–47, 48–63, 64–79, 80–97). In fact, one of the stated aims was that doors and people should "provide an unstressful test that is acceptable to a wide range of subjects, extending from patients suffering from dementia or dense amnesia to healthy young normal subjects" (Baddeley et al., p. 4). However, some elderly, cognitively impaired subjects may find this test quite demanding.

7.07.10 ASSESSING LANGUAGE DYSFUNCTION

In normal aging, deterioration of language has been considered to be either very marginal or a consequence of deterioration of other cognitive functions. Although the majority of elderly people do not develop any gross language disturbance, close scrutiny suggests that some subtle changes are indeed present (Kemper, 1992). In contrast, language deficits are a very pronounced aspect of cognitive deterioration in DAT. Aspects of language may also be disrupted by other forms of cortical and subcortical dementias (e.g., fronto-temporal dementias, Huntington disease, Parkinson's disease, vascular dementia, etc.).

Given the frequency of occurrence of language disorders after degenerative neurological diseases associated with old age, language should be investigated in depth. In the following sections, the most frequent language disturbances encountered either in normal aging or as a consequence of degenerative disorders will be reviewed briefly and suggestions made about appropriate assessment procedures. The examination of language competence should include assessment of verbal expression (naming, vocabulary, discourse and verbal fluency, repetition, prosody), verbal academic skills (reading, writing, spelling), and verbal comprehension (syntax, idioms, and proverb interpretation). As yet there is no comprehensive battery specifically designed for assessing language abilities in the elderly, therefore clinicians often fall back on general aphasia batteries. This can be problematic as the norms for the elderly are limited. In addition there is a need to derive individual comparison standards when assessing language function because of the large degree of variability in premorbid competence (see Section 7.07.4.1). Therefore, examiners should devote time in their initial interview to inquire about factors such as educational level, previous occupation, and reading habits.

7.07.10.1 Naming

Everybody has personal experience of looking for the name of an object, having a very strong feeling of exactly knowing what one wants to say but being unable to recall the correct word. This phenomenon is often referred to as "tip of the tongue." Word finding difficulty is the most common language symptom experienced by healthy people over 60 (Burke, Mackay, Worthley, & Wade, 1991). It is experienced occasionally by young people, but aging seems to exacerbate the problem. The standard task for assessing word finding abilities is confrontation naming, in which subjects are required to name a given object, or more commonly, to name objects depicted in line drawings. One of the most popular tests is the Boston Naming Test (BNT) (Kaplan, Goodglass, & Weintraub, 1983). The original version of this test included 85 items (Kaplan, Goodglass, & Weintraub, 1978); however, the shortened version produced in 1983 is used more frequently. This test consists of 60 line drawings of objects of graded difficulty, ranging from very common objects (e.g., a tree) to less familiar objects such as an abacus. Although the original normative data are scanty, several studies have provided supplementary norms; these studies have been reviewed comprehensively by D'Elia et al. (1995). Data collected from a large sample of 750 older adults (over the age of 55 years) showed that performance on the BNT was influenced by age which accounted for more than 10% of the raw score variance (Ivnik, Malec, Smith, Tangalos, & Petersen, 1996).

A study carried out with patients showed that correlation between the two (long and short) forms of the test and two 42-item forms (obtained by dividing the original test into two nonoverlapping forms) ranged from 0.96 to 0.92 (Huff, Collins, Corkin, & Rosen, 1986). A study (Mitrushina & Satz, 1995) carried out with healthy elderly individuals has reported that repeated testing with the BNT reveals a high stability of scores over time, suggesting a lack of practice effects.

Naming may also be assessed using the Object Naming Test (Newcombe, Oldfield, Ratcliff, & Wingfield, 1971) or the Graded Naming Test (Warrington, 1984). A detailed examination of naming should also include naming of actions (verbs), body parts, and colors. Naming of actions may be tested by means of formal action naming tests (McCarthy & Warrington; 1986; Obler & Albert, 1978). As an alternative, the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1987) provides a comprehensive examination of naming abilities. However, this test is time-consuming and is best suited to highly experienced examiners; furthermore, there is limited normative data for the healthy elderly.

Confrontation naming studies based on the BNT indicate that there is an increase in the variability of scores among apparently healthy individuals in their 60s, thereby suggesting impairment in a subset of this age group (Van Gorp, Satz, Kiersch, & Henry, 1986). There is consistent evidence of a steep decline in the late 70s (Goodglass, 1980; Mitrushina & Satz, 1995). This decline is evident with both low-frequency nouns and verbs but is more marked in the former (Obler, Albert, & Goodglass, 1981). Poor scores on confrontation naming can arise because of a failure to give any response or because of incorrect responses. Increases in the number of errors on confrontation naming tasks were observed in a couple of studies that compared the performance of over 80-year-old subjects with younger subjects (60- and 70-year-olds) (Albert, Heller, & Milberg, 1988; Borod, Goodglass, & Kaplan, 1980). Obler and Albert (1985) analyzed the qualitative features of errors made by the elderly and noted that they tend to be characterized by the use of circumlocutions.

Naming can also be studied using verbal fluency tasks which require the generation of words from semantic or phonemic cues. These tasks are reviewed in Section 7.07.13.2. Two hypotheses have been put forward to explain the naming problems that occur with normal aging. One argues for a degradation in the structure of lexical knowledge, whilst the other argues for an impairment in retrieval mechanisms (see Light, 1992 for a review). Experimental evidence shows that semantic priming effects are virtually identical for young and healthy older adults (Balota & Duchek, 1988; Burke, White, & Diaz, 1987; Monti et al., 1996); further, in naming tasks, performance both of young and old subjects is enhanced more by phonological cues than by semantic cues (Nicholas, Obler, Albert, & Goodglass, 1985). These findings suggest that structural semantic knowledge of words is intact and that a deficit of retrieval or access to this knowledge may be responsible for word-finding difficulties.

The situation is more complicated when trying to understand the severe word-finding difficulties that occur in DAT. Conflicting explanations have been provided for this, and evidence in favor of an access or retrieval deficit (Kempler, 1988; Neils, Brennan, Cole, Boler, & Gerdeman, 1988), or evidence of a structural disruption (Hodges, Patterson, Graham, & Dawson, 1996; Kempler, Andersen, & Henderson, 1995; Nebes, Brady, & Huff, 1989) has been reported. Further, in demented people, failure on confrontation naming could be due to visuoperceptual deficits that result in failure to identify and recognize an object, as suggested either by the fact that performance improves when additional sensory cues are provided (Barker & Lawson, 1968) or by the fact that errors consist of naming objects which are visually rather than semantically related to the target.

7.07.10.2 Vocabulary

As discussed earlier, structural knowledge about words does not change greatly in the normal elderly population, and vocabulary scores do not typically decrease in the normal aged (Salthouse, 1988), rather they may increase, albeit modestly. This evidence supports the notion of a preserved structural knowledge of words in the normal aged population. The most widely used instrument for the assessment of vocabulary ability is the Vocabulary subtest of the WAIS-R (Wechsler, 1981) which consists of 35 items organized in order of increasing difficulty. Performance on this test is greatly influenced by education (Malec, Ivnik, Smith, & Tangalos, 1992) and socio-cultural factors (Huttenlocher, Haight, & Bryk, 1991) rather than age. A test–retest reliability coefficient of 0.71 has been reported in a study of the healthy elderly (Snow, Tierney, Zorzitto, Fisher, & Reid, 1989).

7.07.10.3 Discourse

The assembling of a meaningful and well-structured discourse requires lexical and syntactic competence, including a knowledge of pragmatics (i.e., discourse structure and rules), adequate sequencing skills, including the ability to integrate concepts within and between sentences, and adequate working memory capacity. Material from the clinical interview can be used to assess the quality of discourse and this can be supplemented by asking a patient to describe a standard picture or relate a well-known story (e.g., Little Red Riding Hood). As a standard picture, the Cookie Theft Picture of the Boston Diagnostic Aphasia Examination (Goodglass & Kaplan, 1983) may be used. The examiner should assess whether the production is assembled coherently, if elements are connected and sequenced in the appropriate order, whether an individual makes correct use of reference pronouns, and whether appropriate elements are produced. Performance should also be evaluated in terms of the complexity of sentences, grammar and syntax, and richness of vocabulary.

Aging does not have macroscopic effects on discourse; some subtle deficits, however, may be present in the use of pronouns in discourse, with older subjects using pronouns without specifying their referent in spontaneous speech, a situation that especially involves memory (Pratt, Boyes, Robins, & Manchester, 1989). It has also been reported that deficits on discourse production reflect changes in those macrolinguistic skills that require integration of linguistic and nonlinguistic cognitive processes rather than language-specific cognitive processes (Glosser & Deser, 1992). It was observed that elderly subjects did not differ from young subjects on microlinguistic aspects such as syntactic complexity, lexical production, and use of lexical cohesive ties; however, older individuals failed to refer coherently to the general topic. Discourse production is impaired significantly in patients with DAT, even in the very early stages, and is characterized by incoherence and emptiness of speech; spontaneous speech therefore remains fluent but carries less information (Giles, Patterson, & Hodges, 1996; Ripich & Terrell, 1988).

7.07.10.4 Verbal Comprehension

Comprehension is usually well preserved in healthy elderly individuals, and apparent deficits are often simply a reflection of poor auditory acuity (see Section 7.07.2). The most common test of verbal comprehension is the Token Test (De Renzi & Vignolo, 1962). The original version of this test consists of 62 items but a 36-item short-form (De Renzi & Faglioni, 1978) is more commonly used in clinical practice. The materials consist of tokens which differ in color, shape (squares and circles), and size (large and small). The examinee has to follow verbal instructions which increase in complexity from simple commands (e.g., "Touch a circle," "Touch the red circle") to commands such as "Before touching the yellow circle, pick up the red square." The test authors recommend that scores be adjusted for years of education. Adjusted scores of 25–28 are regarded as indicating mild comprehension problems and 17–27 moderate problems; scores below this are classified as severe or very severe. This test is extremely sensitive to impairment of linguistic processes. De Renzi and Faglioni (1978) reported a true positive classification rate of 93% when assessed against results from an extensive aphasia examination; the true negative rate was 95%.

Test–retest reliability with aphasic patients is very high, ranging from 0.92 to 0.96 (Gallagher, 1979; Orgass, 1976). There are inconsistent reports about the effects of age and education on performance, some suggesting a moderate increase in number of errors with aging (see Lezak, 1995).

Memory and attention play an important role in performance on comprehension tests. For example, working memory load is high on the later items of the Token Test. Therefore, results obtained from measures of attention and memory must be integrated with the results from tests of comprehension when reaching a formulation regarding the nature of an individual's difficulties.

7.07.11 ASSESSING VISUOPERCEPTUAL DYSFUNCTION

Visuoperceptual deficits represent a very common finding in sufferers of degenerative cortical illnesses. A comprehensive evaluation of visuoperceptual abilities should include assessment of color perception, visual recognition, visual organization, and visual interference. A first step in assessing visuoperceptual functions should be to test for the presence of unilateral neglect; this topic is covered in Section 7.07.12.1.

7.07.11.1 Visual Recognition

Evaluation of visual recognition abilities includes assessment of several aspects. It includes, first of all, assessment of perception of angulation. The most widely used test in this case is the Judgment of Line Orientation Test (Benton, Hannay, & Varney, 1975). This test includes 30 pairs of angled lines to be matched with the corresponding lines in a radially arranged 11-line display. An advantage of this test over many clinical tests used to assess visuospatial functioning is that it imposes minimal demands on praxic, mnestic, or executive functions. The norms include correction factors for age and education but are based on only 144 subjects. Age effects on this test have been confirmed by Eslinger and Benton (1983); test–retest reliability over a one-year delay in an elderly sample was modest ($r = 0.59$) (Levin et al., 1991).

The recognition of objects depicted under conventional and unusual views should be examined. Warrington and Taylor's (1973) Unusual Views Test can be used for the latter. Assessment of visual recognition also includes testing of face recognition abilities. For this purpose the Benton Facial Recognition Test (BFRT) (Benton, Hamser, Varney, & Spreen, 1983; Benton & Van Allen, 1968) may be administered. The original version of this test includes 22 items; it is a matching task rather than a true recognition task since it requires matching a front-view photograph of a target face to a matrix of faces photographed either in front-view, three-quarter-view, or under different lighting conditions. Norms are available up to the age of 74 years. Some degree of age-related decline in performance on this test has been observed (Benton, Eslinger, & Damasio, 1981) and the norms have correction factors for age and education. Further evidence of age-associated impairment at several stages of the face recognition process has been reported (Maylor, 1990). It should be noted that prosopagnosics can perform within normal limits on the BFRT. However, they take an inordinate amount of time per trial as their performance is characterized by a piecemeal strategy in which each feature of the target face is compared with each feature of the faces in the matrix (Ellis, 1992).

7.07.11.2 Visual Organization

Making sense out of fragmented, incomplete, or ambiguous figures requires intact visual organization abilities. Those abilities may be tested using tasks such as the Street Completion Test (Street, 1931) or the Hooper Visual Organization Test (HVOT) (Hooper, 1983). The HVOT requires examinees to name 30 fragmented objects. Test–retest reliability in an elderly sample was 0.68 (Levin et al., 1991) and the original norms cover up to age 68 years. Studies which have investigated this task in elderly subjects (55–92 years of age) indicate that performance drops off significantly with age (Farver & Farver, 1982; Montgomery & Costa, 1973; Villardita, Cultrera, Cupone, & Mejia, 1985).

7.07.11.3 Visuoconstructional Ability

Visuoconstructional abilities are usually assessed by means of copying or free drawing. The Rey-Osterreith Complex Figure (Osterreith, 1944) is the most widely used copying test (for further details see Section 7.07.9.4.5). The Block Design subtest of the WAIS-R may be used for assessing two-dimensional constructional abilities.

7.07.11.4 Visual Interference

Visual interference may be evaluated by means of the Hidden Figures Test (Gottschaldt, 1928) which requires a subject to recognize a simpler figure, hidden in a more complex one, by marking its outline. Normative data up to the age of 79 years are provided in Spreen and Strauss (1991). Another useful and well-known task for assessing visual interference is the Overlapping Figure Test (Poppelreuter, 1917). An effect of normal aging on performance on this test has been reported in a recent study (Della Sala, Laiacona, Trivelli, & Spinnler, 1995) in which severely impaired performance was observed in a sample of patients with DAT.

7.07.12 ASSESSMENT OF ATTENTION

7.07.12.1 Unilateral Neglect

Unilateral cerebral lesions (especially right parietal lesions) often results in unilateral neglect. Neglect labels a phenomenon that involves lack of awareness of stimuli appearing on the side contralateral to the cerebral lesion. It is accepted widely that neglect is not a unitary phenomenon and evidence of dissociations across modalities within the same patient and between patients have been reported (Halligan & Robertson, 1992).

Assessment of neglect should explore representational and motor abilities as well as visuospatial abilities. Personal (relating to the subjects body), peripersonal (within arms length), and extrapersonal space should be investigated. A dissociation between personal peripersonal space and extrapersonal space has been illustrated by Halligan and Marshall (1991) who described a case with severe neglect in the former spheres but who nevertheless failed to exhibit neglect for distant experimental stimuli and could aim successfully at areas on a dart board which were to the left of the midline.

The most frequently administered test for assessing visuospatial exploration is the Albert Test (Albert, 1973) which consists of 40 lines drawn out at various angles on a sheet of paper; the subject's task is to cross out all of them. Normal subjects usually perform flawlessly on this test. Neglect may also be assessed using the Bells Test (Gauthier, Dehaut, & Joanette, 1989) that includes 315 silhouettes of common objects, of which 35 are bells; the subject's task is to search for the bells. Normative data (including data from subjects aged 50–89 years) are available for this test, and no more than three bells are usually missed by normal elderly subjects. Test–retest reliability over a two-week period was reported as 0.69.

Line Bisection is also a widely used task for assessing neglect; it requires a subject to divide horizontal lines at the center point. Performance on this task can be highly variable, and it is advisable to acquire data from multiple trials. Patients with right hemisphere lesions show a right-deviation error of the bisection point, that increases as a function of the length of the line (Halligan & Marshall, 1989).

Representational neglect, that involves mental imagery, may be assessed by asking a patient to describe a well-known scene from a particular perspective. A patient may fail to recall objects on the left but recall the same objects when asked to imagine the scene from the opposite perspective (Bisiach & Luzzatti, 1978).

A comprehensive battery for testing visual neglect has been assembled by Wilson, Cockburn, and Halligan (1987). This battery is called the Behavioural Inattention Test (BIT) and includes conventional tests (star cancellation, letter cancellation, figure copying, line crossing, line bisection, and representational drawing) and behavioral subtests (picture scanning, telephone dialing, menu reading, article reading, telling and setting the time, coin sorting, address and sentence copying, map navigation, and card sorting). The test manual reports impressively high coefficients for inter-rater reliability (0.99), test–retest reliability (0.99) and parallel form reliability (0.91). Among the six conventional tests included in the battery, star cancellation had substantially greater sensitivity than the other tests (Halligan & Marshall, 1988) (see Figure 1).

Although many studies have explored the performance of normal subjects on some of the tests commonly used to assess neglect, relatively little is known about the effect of normal aging and dementia on these tasks. Neglect is seldom found in DAT, despite the frequency of visuoperceptual disorders in this condition; Huff et al. (1987) reported an incidence of 3% based on 95 cases. A high incidence of neglect has been reported by one study of visuospatial ability in DAT (Freedman & Dexter, 1991). These authors concluded that neglect in DAT may not be an unusual phenomenon but could often be missed because of a failure to conduct a detailed assessment. However, it should be noted that neglect was considered to be present if the discrepancies between errors on left- vs. right-sided stimuli on visuospatial tasks exceeded control values (these control values were simple difference scores). As there typically will be a high number of errors on visuospatial tasks in DAT cases, and often they will exhibit considerable intrasubject variability, these results may be an artifact of Freedman and Dexter's (1991) scoring methods. This alternative explanation is strengthened by the fact that the number of cases classified as exhibiting right-sided neglect was exactly equivalent to the number classified as exhibiting left-sided neglect (right-sided neglect is relatively rare). When looking at individual reports of cases of DAT displaying neglect, only three cases have been reported (Ishiai, Okiyama, Koyama, & Seki, 1996; Pentore & Venneri, (1994). Pentore and Venneri (1994) in their study reported two patients with DAT of moderate severity who manifested neglect in the later stages; one of these patients manifested motor neglect in addition to visuospatial neglect. Such limited evidence may lead to the conclusion that neglect in DAT is actually rather rare. This would be in accord with the fact that neglect is generally observed after unilateral lesions, while DAT, although it may present some degree of asymmetry at onset, involves bilateral degeneration (see Kirk & Kertesz, 1991, for further discussion).

7.07.12.2 The Anterior Attention System

The anterior attention system is considered to underlie performance on tasks of sustained, divided, and selective attention (Posner & Petersen, 1990). Such attentional problems are common and debilitating features of many neurological and psychiatric disorders associated with aging (Crawford, McKinlay, & Parker, 1992b; Lezak, 1995; Walsh, 1991). However, the assessment of attentional dysfunction is a problematic area in clinical neuropsychology as many potentially useful tasks used in experimental studies have not been translated into practical clinical instruments. Many existing tests do not reflect theoretical knowledge on attention and its fractionation (Posner & Petersen, 1990) and, in many cases, are poorly standardized (Lezak, 1995). An additional consideration is that tests such as the PASAT, which have proved valuable in work with younger clinical populations because of their demonstrated sensitivity and predictive validity, are too demanding to be suitable for use with the majority of elderly clients. Because of space limitations, we will limit coverage to a single battery, the Test of Everyday Attention

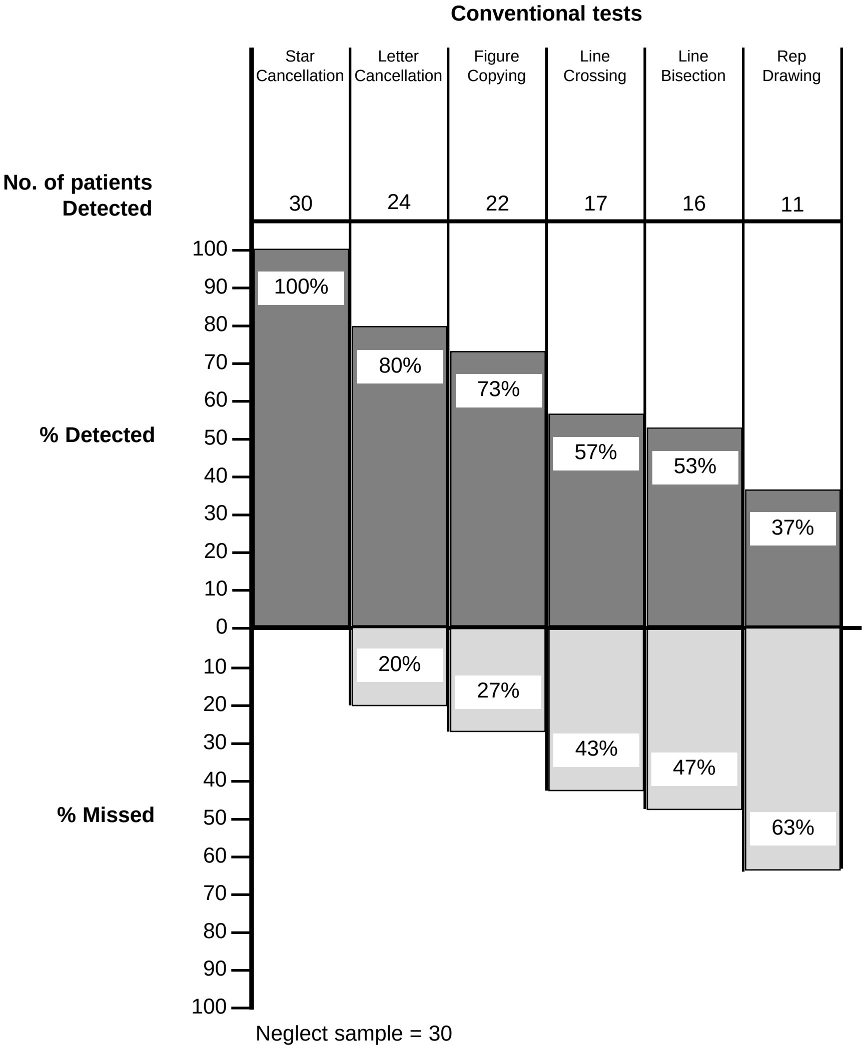

Figure 1 The relative sensitivities of the six conventional screening tests of the Behavioral Inattention Test (reproduced from Halligan & Robertson, 1992).

(TEA) (Robertson, Ward, Ridgeway, & Nimmo-Smith, 1994; Robertson, Ward, Ridgeway, & Nimmo-Smith, 1996).

TEA is a welcome development as it attempts to overcome some of the aforementioned problems in the assessment of attentional dysfunction. It consists of eight subtests, standardized to have means of 10 and SDs of 3, which measure sustained, selective, and divided attention. For example, in the Map Search subtest, which was designed as a measure of visual selective attention, the examinee has to search for symbols (e.g., a knife and fork representing eating facilities) on a tourist map of a city. The Elevator Counting subtest, which was designed to measure sustained attention, is a tone counting task in which the examinee is asked to imagine they are in an elevator in which the floor indicator has failed (thus counting the tones is the only way to establish which floor the elevator is on). A related subtest, designed to measure auditory selective attention, requires the examinee to ignore distracter tones which are of a higher pitch.

The TEA was normed on 154 healthy participants aged 18–80 years. In addition to reflecting current thinking on the fractionation of attention, it is designed to be ecologically valid, that is, many of the subtests are designed to mimic everyday activities. Another advantage is that it has three parallel versions; this avoids the interpretative problems encountered when attempting to measure change using the same test materials.

Crawford, Somerville, and Robertson (1997) have prepared tables which allow clinicians to examine a client's relative strengths and weaknesses on the TEA (in terms of the reliability and abnormality of subtests deviations from the subtest mean), thereby supplementing the conventional normative comparison standards presented in the test manual with individual comparison standards.

7.07.13 ASSESSMENT OF EXECUTIVE FUNCTIONS

Executive deficits arising from damage to the prefrontal cortex and related structures can have a much more profound effect on a client's prospects for successful adjustment and independent living than the more circumscribed deficits arising from posterior cortical lesions. However, these problems have proven difficult to quantify and as such can be regarded as constituting the most problematic area in neuropsychological assessment. For example, reviews of tests such as the Wisconsin Card Sorting Test (Grant & Berg, 1948; Heaton, 1981), which are aimed specifically at capturing the core cognitive problems (e.g., planning deficits, underutilization of feedback, etc.), indicate that existing indices are of limited utility when used with individuals (Mountain & Snow, 1993; Reitan & Wolfson, 1994). Thus, considerable reliance must be placed on careful scrutiny of a client's approach to a range of tasks to identify these cognitive difficulties.

7.07.13.1 Frontal Hypotheses

Executive deficits are thought to underlie many of the behavioral disturbances seen in neurological disorders associated with increasing age. One of the more obvious examples is Parkinson's disease (PD). Executive deficits would be expected in PD on pathophysiological grounds as the basal ganglia, which are deprived of dopaminergic innervation because of degeneration in the substantia nigra, have strong reciprocal connections with the frontal cortex. In addition, the ventral tegmental area, which provides a direct dopaminergic innervation of the prefrontal cortex, also deteriorates in PD (see Crawford, Besson & Ebmeier, 1990 for brief review). There is neuropsychological evidence which suggests that executive deficits are an early feature in PD and that these deficits qualify as differential deficits in executive functioning (Lees & Smith, 1983). Indeed, it has been argued that fronto-executive dysfunction provides a parsimonious explanation for all of the cognitive deficits observed in nondemented Parkinson's cases (Della Sala, 1988). This is an extreme position but it is interesting to note that Bondi, Kaszniak, Bayles, and Vance (1993) have demonstrated that deficits in other cognitive domains were no longer significant after partialing out performance on tests of executive function.

It has also been proposed that normal aging is associated with a selective decline in fronto-executive function (Dempster, 1992). Daigneault, Braun, and Whitaker (1992), for example, note that "The currently dominant neuropsychological model of normal brain aging postulates that cognitive functions dependent on the integrity of the prefrontal brain regions are among the first to deteriorate" (p. 99). This frontal hypothesis stems from indications that age-related changes in the neuroanatomy and neurochemistry of the brain are more pronounced in the frontal lobes than in other cortical areas (Fuster, 1989) and from demonstrations of age-related deficits on neuropsychological tasks sensitive to frontal dysfunction (Daigneault & Braun; 1993; Daigneault et al., 1992; Mittenberg, Seidenberg, O'Leary, & DiGiulio, 1989). However, there is only limited evidence that such deficits qualify as differential deficits (i.e., that they significantly exceed the deficits found in other cognitive domains).

7.07.13.2 Verbal Fluency

Verbal fluency tests, and in particular initial letter fluency, are widely used as tests of executive dysfunction (Parker & Crawford; 1992; Walsh, 1991). Initial letter fluency, also referred to as the Controlled Oral Word Association Test (COWAT) (Benton; 1969) or phonemic fluency, requires the generation of words from initial letters (normally F, A, and S or C, F, and L) under time constraints (normally 60 seconds per letter, although 90 seconds is also used). Fluency tests are reliable, quick to administer, and even patients with quite severe deficits can understand the task requirements. In an area replete with failures to replicate, studies of initial letter fluency have been remarkably consistent in demonstrating impaired fluency following left or bilateral damage (Benton, 1968; Bornstein, 1986; Miceli, Caltagirone, Gainotti, Masullo, & Silveri, 1981; Miller, 1984; Milner, 1964). In view of the above, fluency tests are among the most useful tests in the clinician's armamentarium.

Performance on verbal fluency tasks reflects the integrity of the semantic system (i.e., the system responsible for storage of words and their associations), the efficiency of retrieval strategies, and the efficiency of self-monitoring and inhibition of inappropriate responses. In an early influential paper, Perret (1974) reported significant deficits on initial letter fluency in patients with focal frontal lesions whilst noting that semantic or category fluency (i.e., generating exemplars from categories such as animals, fruits, etc.) often failed to expose deficits (Newcombe, 1969). Perret (1974) and others have argued that the differential sensitivity of initial letter fluency to frontal dysfunction stems from the fact that in everyday life words are retrieved predominantly on the basis of their meaning. Thus, initial letter fluency is relatively novel and places greater demands on strategy generation and inhibition of semantic associates. In contrast, semantic fluency places greater demands on the integrity of the semantic system. Hodges, Salmon, and Butters, (1990), for example, is one of many studies in which there was evidence of a differential deficit in semantic fluency vs. initial letter fluency in DAT. This is consistent with other evidence indicating that deterioration of the semantic system is a marked feature of DAT (e.g., Grober, Buschke, Kawas, & Fuld, 1985).

Further support for this distinction comes from dual task studies of initial letter and semantic fluency in healthy participants. Martin, Wiggs, Lalonde, and Mack (1994) demonstrated that a secondary task involving motor sequencing (designed to activate frontal cortex) produced a differential deficit in initial letter fluency, whereas a secondary task involving semantic decisions regarding visual stimuli (designed to activate posterior cortex) produced a differential deficit in semantic fluency.

Some very useful normative data for the elderly have been published. Ivnik et al., (1996) present age- and education-based norms based on 743 elderly participants using the COWAT (i.e., the letters C, F, and L with 60 seconds per trial). Particularly positive features of these data are the age range covered (55–97 years) and the fact that most participants were also administered other commonly used neuropsychological instruments. This latter feature makes the data useful when attempting to construct a profile of a client's relative strengths and weaknesses as raw scores are converted to a common Scale and there is no worry that observed discrepancies are artifacts of differences between normative samples (see Section 7.07.4.2). Kozora and Cullum (1995) have published elderly norms for initial letter fluency (F, A, and S) and semantic fluency covering the age range 50–90 years. The semantic fluency test used was the supermarket item list from the Mattis Dementia Rating Scale (Mattis, 1988).

Errors on verbal fluency tasks have been afforded great significance in both the research literature and in advice offered to clinicians (Walsh, 1991). Perseverative errors (repeating a word produced previously) and rule-break errors (e.g., producing a proper noun or a word beginning with the wrong letter on initial-letter fluency trials) have been regarded as evidence of disinhibition or a failure of self-monitoring (Crowe, 1992; Walsh, 1991). Crowe (1992) has produced data to suggest that such errors tend to be associated with orbito-frontal damage, whereas impoverished but legitimate output is more indicative of damage to the lateral convexity.

Given the importance attached to such errors, there is surprisingly little normative data on errors to assist clinicians interpret an individual client's performance. Kozora and Cullum's (1995) study provided means and ranges for perseverative and rule-break errors. Although the mean and modal rates were low in all age bands, a finding consistent with a COWAT normative study conducted by Ruff, Light, Parker, and Levin (1996), the ranges are quite substantial (e.g., 0–15 in the 50–59 age group). It would be useful to know how many errors are required to exceed the 85th or 95th percentiles of the healthy population but there is no relevant published data.

There is a strong relationship between verbal fluency and general verbal ability in the general population. For example, Miller (1984) reported a correlation of 0.87 between initial letter fluency and Verbal IQ in a healthy sample ($N = 30$). Crawford, Obonsawin, and Bremner (1993) reported a lower but still substantial correlation of 0.64 between Wechsler Verbal IQ in a sample of 144 healthy participants. This indicates that an individual's premorbid verbal ability must be considered as an important factor when interpreting fluency performance in clinical populations. This was graphically illustrated by Borkowski, Benton, and Spreen (1967) who reported that the fluency performance of a "brain-damaged" sample of above average verbal IQ was significantly higher than the performance of healthy subjects of below average verbal IQ. Crawford et al. (1992c) have provided a NART-based regression equation which provides an estimate of a client's premorbid fluency performance (see Section 7.07.8 for details of the NART). This equation was derived from a healthy sample ($N = 142$) with an age range of 16–88 years.

7.07.13.3 Nonverbal Fluency

A number of attempts have been made to develop methods of assessing nonverbal fluency. Jones-Gotman and Milner (1977) developed a task they termed Design Fluency which requires examinees to draw abstract (nonsense) designs under a time constraint. This test can capture the lack of creativity and spontaneity and the perseverative tendencies which are often striking clinical features of patients with frontal damage. The disadvantages of this test include the lack of adequate normative data, the highly subjective nature of scoring, and the fact that it can be difficult to maximize cooperation, either because clients fail to grasp the nature of the task or view it as odd and lacking in relevance.

Ruff and colleagues (Ruff, 1988; Ruff, Light, & Evans, 1987) have developed a figural fluency test (hereafter RFFT) which requires the examinee to join up a repeating sequence of dots such that each design formed is unique. The procedure removes subjectivity from scoring as each design is unequivocally unique, a perseveration, or (more rarely) an error. The RFFT was normed on a sample of 358 healthy individuals with an age range of 16–70 years. Group studies of clinical populations indicate that the RFFT is sensitive to anterior cerebral damage, particularly in the right hemisphere (Lee et al., 1997; Ruff, Allen, Farrow, Nieemann, & Wylie, 1994). For example, Lee et al. found that 35% of designs produced by a group with right frontal lesions were perseverations, a figure which substantially exceeded the rate in right temporal (14%) and left frontal (17%) cases.

Motor slowing is a common consequence of cerebral damage and should be considered as a factor when interpreting the number of legitimate designs produced on the RFFT. Ruff, Evans, and Marshall (1986) have reported that significant RFFT deficits are observed in neurological samples after controlling for motor speed using a finger-tapping test. However, the appropriateness of finger-tapping as a control measure could be questioned. Crawford, Wright, and Bate (1995) used a simple motor task which required subjects to join repeated pairs of dots; the motor demands of this task are very similar to the RFFT but it does not require the generation of designs. They reported that the RFFT deficit in a head-injured sample did not significantly exceed the deficit on the motor task.

7.07.13.4 Behavioral Assessment of the Dysexecutive Syndrome

A very useful battery for assessing executive problems has been developed (Wilson, Alderman, Burgess, Emslie, & Evans, 1996; Wilson, Evans, Emslie, Alderman, & Burgess, in press). The Behavioral Assessment of the Dysexecutive Syndrome (BADS) battery consists of six subtests and was normed on a sample of 216 healthy participants with an age range of 16–87 years. As was noted previously, many of the formal neuropsychological tests can fail to detect executive problems because they are highly structured. Shallice and Burgess (1991) note "The patient typically has a single explicit problem to tackle at any one time ... the trials tend to be very short ... task initiation is strongly prompted by the examiner and what constitutes successful trial completion is clearly characterized" (pp. 727–728). Although some of the tests reviewed above clearly attempt to deviate from this formula, the BADS represents the most ambitious and systematic attempt to date to capture the core elements of dysexecutive syndromes.

The BADS subtests include the Rule Shifts Cards Test in which a previously established response set (responding "yes" to red cards, "no" to black) has to be inhibited in favor of responding in terms of whether or not a card matches the color of the card immediately preceding it. The Action Program Test is a planning task in which the solution requires the client to utilize various everyday materials (e.g., plastic, cork, and wire). The Modified Six Elements Test (see Shallice & Burgess, 1991) assesses scheduling and time management by requiring clients to tackle three different tasks within the time limit; there are two versions of each task and the rules prohibit tackling these contiguously.

The inter-rater reliability of the BADS is excellent; correlations between raters ranged from a low of 0.88 on one index from the Modified Six Elements Test, to unity, or near unity, on most of the other tasks. Test–retest reliability coefficients obtained from a small subset of the standardization sample (retested over a 6–12 month interval) ranged from modest to poor but this, in part, reflects the effects of range restriction.

A useful supplement to the formal BADS subtests is the Dysexecutive Questionnaire (DEX). The DEX covers dispositional and cognitive changes and comes in two forms, one for completion by the client, the other by a relative or carer. A provisional factor analysis indicates that the DEX measures three broad factors labeled as "Behavior," "Cognition," and "Emotion." Large discrepancies between client and carer reports of change are common when working with clients who have executive problems. The DEX provides one means of quantifying this lack of insight; DEX results can also form a basis for discussion when counseling clients and their families.

The DEX has been used to examine the relationship between carers' ratings of executive problems and formal test scores. Multiple regression analyses found that BADS scores were the only significant predictors of rated problems from among a set of measures which included traditional "frontal" tasks and measures of current and premorbid general intellectual ability.

7.07.14 THE DIFFERENTIAL DIAGNOSIS OF DEMENTIA VS. DEPRESSION

The differential diagnosis of dementia vs. depression has been described as "probably the knottiest problem of differential diagnosis" (Lezak, 1995), yet is a common reason for elderly patient referral to clinical psychologists. Depression is the functional disorder which can most closely resemble the early stages of a dementing condition. It is vitally important for an accurate differential diagnosis to be made because as Woods and Britton (1985) point out, "Depression can be treated; dementia typically leads to therapeutic despair." Des Rosiers (1992) reviewed 18 studies and reported that, on average, 10% of cases initially diagnosed as organic dementia were later rediagnosed as depression. In practice, the diagnosis of dementia vs. depression is made by drawing on information from a wide variety of sources, that is, previous history, informant's account, phenomenology, brain scan measures, blood biochemistry, etc. Problems emerge, however, when an individual presents with no well-documented history and no useful informant information.

Huppert (1994) has pointed out that in most studies where an early DAT group has been compared with a control group, it is likely that the controls vary from the demented subjects in ways which are rarely specified. For example, as the normal controls are usually community volunteers, they are less likely to have mobility problems than sensory deficits and are more likely to be in good health. The patients usually have been referred to specialists which means that dementia is sufficiently severe to have come to specialist attention, and second, that the patients who see specialists may not be representative of all demented subjects. As Huppert (1994) states "one implication of these considerations is that observed differences are likely to be an exaggeration (if not a distortion) of the performance which would be seen in a genuinely representative sample" (p. 295).

7.07.14.1 Delayed Verbal Recall Impairment as an Indicator of Early DAT?

Over the years there have been many attempts at using memory tests to help distinguish between dementia and depression. In order to highlight the problems associated with this approach, in the following section the Delayed Word Recall test will be used as an example.

In two studies by the consortium to establish a registry for DAT (CERAD), the investigators reported that delayed verbal recall was a highly sensitive indicator of early DAT (Morris et al., 1989; Welsh, Butters, Hughes, Mohs, & Heyman, 1992). In DAT, there appears to be a rapid rate of forgetting within the first 5–10 minutes following acquisition (Butters et al., 1988; Hart, Smith, & Swash, 1988) but a relatively normal rate of forgetting thereafter (Corkin et al., 1984; Kopelman, 1985). Knopman and Ryberg (1989) suggested that elaborative encoding may provide a substantial benefit in normal elderly individuals but not to patients with DAT. They proposed that the optimum memory test procedure for the early diagnosis of DAT should involve: (i) a study phase in which subjects were required to engage in elaborative encoding; (ii) a filled delay interval; and (iii) a test phase which involved free recall. Accordingly, Knopman and Ryberg (1989) developed the Delayed Word Recall test (DWR). Ten nouns are presented on cards, one at a time (chimney, salt, harp, button, meadow, train, flower, finger, rug, book). For each word, the subject is asked to read out the word and try to remember it and then to make up a sentence using the word. When all 10 words have been presented, the complete procedure is repeated, with subjects instructed to produce an alternative sentence. Following a five minute filled delay, free recall for the 10 words in the list is tested. Based on the delayed free recall cut-off score of less than or equal to 2 out of 10 = DAT, Knopman and Ryberg (1989) reported an overall predictive accuracy of 95% in a group of DAT patients vs. elderly control subjects. This is an extremely impressive degree of between-group separation.

In a follow-up study, Coen et al. (1996) compared a group of mildly demented DAT patients with individually matched healthy controls and found that the DWR recall measure achieved 98% overall accuracy (i.e., almost perfect between-group separation). In an extension to the original DWR, Coen et al. included a four-choice recognition memory test and, using a cut-off score of less than or equal to 9 out of 10 = DAT, greater than nine = controls, they reported that the recognition measure yielded a sensitivity of 98%, specificity of 95%, and an overall accuracy of 96%. Taken together, the results of the Knopman and Ryberg (1989) and Coen et al. studies suggests that the DWR is an extremely promising measure to aid in the early detection of DAT.

However, for any neuropsychological test index to have clinical utility, the method must be shown clearly to identify patients suffering from DAT without producing false-positives from an elderly depressed comparison group. Unfortunately, too many studies have appeared which have focused on the simple comparison between DAT and very healthy controls, and this criticism can be leveled at the Knopman and Ryberg (1989) and Coen et al. studies.

O'Carroll, Conway, Ryman, and Prentice (1997) attempted to test the utility of the DWR in separating patients with DAT from patients with major depression. Fifty patients with DAT were compared with 50 patients who fulfilled *DSM-IV* criteria for a major depressive episode. While there were highly significant differences in mean free recall and recognition scores, the between-group overlap was large (e.g., see Figure 2 for free recall results—very similar results were obtained for recognition). Put simply, if the recommended cut-off point for free recall of 2 or less out of 10 = DAT is adopted, 44% depressed patients would be misclassified as suffering from DAT. Using the less than 10 recommended cut-off score for recognition score, 48% of depressed patients would be misclassified as suffering from DAT. This study highlights the degree of cognitive impairment which often presents in elderly depressed patients which can masquerade as "pseudo-dementia" (Robbins, Joyce, & Sahakian, 1992).

7.07.14.2 Kendrick Cognitive Tests for the Elderly

The Kendrick Cognitive Tests for the Elderly (KCTE) comprise two components, a pictorial memory task (the Object Learning Test or OLT) and the Digit Copying Test (DCT). The principle underlying the use of the KCTE in differential diagnosis lies in the expected pattern of visual memory and psychomotor speed in depression vs. dementia. According to Kendrick, Gibson, and Moyes (1979), both DCT and OLT should be affected in primary dementia and not in depression. An innovation of the Kendrick test is the requirement that the measures be readministered six weeks following the initial assessment. desRosiers (1992) describes this requirement as somewhat less than practical. However, in our opinion, repeat neuropsychological assessment in cases where diagnosis is in doubt represents good clinical practice.

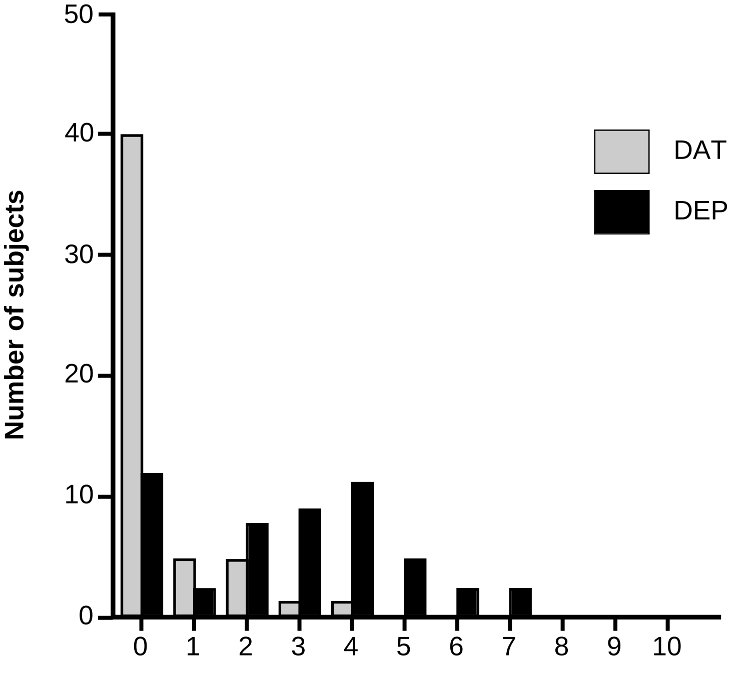

Figure 2 DWR Recall results. Using < 3 recommended cut-offs, only 2 (4%) DAT (Alzheimer) sujects would be misclassified, but 22 (44%) DEP (Depressed) would be classed as DAT (reproduced from O'Carroll et al., 1997).

One of the strongest claims regarding the KCTE is that "it has been found possible to discriminate absolutely between dementias and non-dementing subjects" (Kendrick et al., 1979, p. 329). The literature on the Kendrick test is well reviewed by desRosiers (1992). Some reports have confirmed the utility of the KCTE in differentiating a depressed sample from a demented sample. However, as is usually the case in studies of this sort, the samples consist of very well-defined groups where differential diagnosis is not a problem (Knight & Moroney, 1985). As desRosiers (1992) cautions, the validity of the KCTE should best be examined in patients for whom diagnosis is still ambiguous. A further point to consider when considering the theoretical foundation of the KCTE is the assumption that in depression, psychomotor speed, and mnemonic function are not as detrimentally affected as in early DAT. However, in depressive pseudodementia, it is precisely because both domains are seriously impaired that diagnostic difficulties arise.

7.07.14.3 Effortful vs. Automatic Processing and Memory

Weingartner, Cohen, Bunney, Ebert, and Kaye (1982) proposed that tasks that are normally accomplished automatically and require little cognitive capacity are particularly useful in distinguishing progressive dementia patients from depressed patients. Weingartner (1984, 1986) reported that depressed patients experienced difficulty on memory tasks that require elaborate or effortful organization and processing of material to be remembered, but that they do not show problems in memory tasks on which "automatic" memory encoding is presumed to be involved. In contrast, it is postulated that demented patients have difficulty with both automatic and effortful processing. In line with this proposal, Weingartner, Cohen, Murphy, Martello, and Gerdt (1981) reported that depressed patients demonstrate impairments on delayed free recall (effortful) with no impairment on recognition memory (relatively automatic), whereas demented patients perform poorly in both conditions. However, Lachner, Satzger and Engel (1994) have provided evidence which challenges the Weingartner model. They compared three groups (demented, depressed, and healthy subjects) who were in their 70s on five verbal recall and two recognition memory tasks. They found that both delayed recall and recognition after long delay were the measures which best discriminated between the demented and the depressed patient groups. It is interesting to note that the recognition measure was more discriminating than free recall, selective reminding, or serial learning, all presumably more "effortful" than a recognition task.

Lachner et al. (1994) point out that the labeling of some cognitive tasks as effortful vs. automatic is often ambiguous, and propose sensibly that "In future research, the tasks cognitive capacity requirements should be examined empirically to avoid inconsistencies by subjectively estimating capacity demands" (Lachner et al., p. 10). A particular advantage of the Lachner et al. study is their comparison of severely depressed psychiatric inpatients with a demented patient sample where 60% were still capable of independently running their household, as it is this type of comparison of mildly demented and severely depressed patients that is of particular clinical interest with regard to the problem of differential diagnosis.

7.07.14.4 Is Poor Memory Test Performance in Elderly Depressed Patients an Artifact of Poor Motivation?

In commenting on the relatively poor performance of many depressed patients with standard neuropsychological measures, many writers have attributed this impairment to the nonspecific effects of motivational deficits. Few studies have tested this hypothesis experimentally. One notable exception is the study of Richards and Ruff (1989), who randomly assigned two groups of subjects, depressed and nondepressed, to either motivation or nonmotivation conditions (motivation involved encouragement, a monitory incentive and performance feedback). Richards and Ruff (1989) reported that motivation (as measured by improvement on a simple card-sorting task) was enhanced for the subjects in the motivation condition. Crucially, motivation did not significantly affect neuropsychological test performance and the authors concluded that although depressed patients may be less motivated, this reduced motivation does not fully account for the observed cognitive impairments in depression.

7.07.14.5 Future Directions

The literature indicates that demented subjects are impaired at any task which requires the conscious recollection of newly learned material. However, much work has been carried out attempting to evaluate whether specific aspects of memory functioning are disproportionately impaired in early DAT. Divided attention tasks are particularly sensitive to DAT, that is, tasks where subjects are required to divide their attention during learning (e.g., performing a digit span test while keeping a stylus on a target on a pursuit rotor task). This would appear to be a particular deficit in "working memory," that is, the ability to hold information in a short-term store or carrying out the other processing operations (Baddeley & Wilson, 1986). Additionally, prospective memory tasks appear to be particularly impaired in early DAT. Huppert and Beardsall (1993) administered a variety of memory tasks and found that even patients with minimal dementia were disproportionately impaired on prospective memory tasks (e.g., remembering to ask for a belonging back at the end of the Rivermead Behavioural Memory Test). In the search for particularly dementia-sensitive screening tasks, a combination of divided attention and prospective memory tasks may well be worthy of further investigation.

7.07.14.6 Recommendations and Conclusions for the Differential Diagnosis of Dementia vs. Depression

Sweet, Newman, and Bell (1992) made several useful recommendations to facilitate the differential diagnosis of depressed patients from demented patients. First, they recommend administering neuropsychological measures that assess domains which the literature indicate are particularly discriminating, notably psychomotor retardation, recognition vs. recall, and easy vs. difficult paired associated learning. Second, they recommend utilization of measures of affective status (e.g., the Beck Depression Inventory or the Geriatric Depression Rating Scale). They also propose seeking collateral information through interviewing the spouse or significant other. Third, when evidence of depression is found, customary cognitive "cut-off" scores may be misleading and they propose using more stringent criteria (e.g., an additional standard deviation away from normal performance). Fourth, with depressed patients, they caution against diagnosing brain dysfunction based only on findings such as mild attentional or memory problems. For example, as psychomotor retardation in depression can easily result in a markedly impaired performance on the Stroop task (Trenerry, Crosson, DeBoe, & Leber, 1989), many depressed patients fall within the recommended cut-off score used to indicate "brain damage."

Sweet et al. (1992) also urge against differentiating depression from brain damage after only a single session with the patient and propose seeing the patient on more than one day and, if in doubt, readministering at least a portion of the measures on a second testing session (this would be in accord with the protocol of the Kendrick Cognitive Tests for the Elderly). Sweet et al. conclude "In the event that a diagnostic conclusion regarding brain dysfunction in the depressed patient appears unclear, despite all your best efforts, recommend a re-evaluation of the depressed patient after a period of pharmacological or psychotherapeutic intervention" (p. 41). This is a recommendation that is fully endorsed. Neuropsychological measures should be used in conjunction with information derived from a variety of sources (e.g., relatives and clinical history). Developments in neuroimaging precision suggest that an *in vivo* maker for DAT may become available (Jobst et al., 1994).

Given the potentially catastrophic outcome of misclassifying a treatable, depressed patient as having DAT, it has to be concluded that the available evidence indicates that no single neuropsychological measure can be recommended for use in the individual case to confidently separate early DAT from major depression in an elderly population. However, neuropsychological measures may offer useful information that can be integrated with data gathered from a variety of sources. In particular, accurate objective quantification of change over time is one of the key areas where detailed assessment of cognitive functioning can provide important diagnostic information. Furthermore, changes in neuropsychological status can offer a useful measure of treatment response in both dementia and depression.

7.08.1 INTRODUCTION

Significant progress has been made since the late 1960s with regard to understanding and treating anxiety disorders (Barlow, 1988; Beidel & Turner, 1991). It is now well known that these conditions can have a profound impact on social and occupational functioning, and lifetime prevalence rates have indicated that anxiety disorders are one of the two most common forms of psychiatric disturbance (Robins et al, 1984). The body of knowledge currently available regarding anxiety disorders, however, is focused largely on the younger adult population. Although the need to expand this work to older adults has been emphasized repeatedly (Cartensen, 1988; Hersen & Van Hasselt, 1992; Salzman & Lebowitz, 1991), very little attention had been paid to the nature and treatment of anxiety disorders in this segment of the population. In the late 1990s, a small body of literature has begun to accumulate (Beck & Stanley, 1997; Stanley & Beck, in press). This work will be reviewed here, with particular focus on the prevalence, onset and associated risk factors, psychopathology and differential diagnosis, measurement, and treatment of anxiety in elderly people.

7.08.2 PREVALENCE

7.08.2.1 Anxiety Disorders

The National Institute of Mental Health (NIMH) Epidemiological Catchment Area (ECA) survey documented a one-month prevalence rate of 5.5% for anxiety disorders in older adults (age 65 years or older) (Regier et al., 1988; Regier, Narrow, & Rae, 1990). This figure is slightly lower than the 7.3% rate noted for younger adults, a pattern that mirrors another epidemiological report from Canada (Bland, Newman, & Orn, 1988). Although these figures suggest gradually decreasing rates of clinical anxiety disorders over the life span, they nonetheless indicate that anxiety in elderly people is a significant mental health problem. In fact, in the ECA study, anxiety disorders occurred more than twice as often as affective disorders in older adults, with a frequency four to eight times greater than major depression (Regier et al., 1988; Weissmann et al., 1985). Given the significant attention that has already been focused on depression as a major health problem in the elderly (Reynolds, Lebowitz, & Schneider, 1993), the ECA data emphasize the need for further study of older adults with anxiety problems, particularly those with symptoms which interfere with daily functioning.

The majority of anxiety disorders assigned to older adults within the ECA survey were classified as phobias (4.8%), including agoraphobia, social phobia, and simple phobia. Much lower prevalence rates were documented for obsessive-compulsive disorder (OCD; 0.8%) and panic disorder (PD; 0.1%). At the Yale University site, wherein older adults were oversampled, prevalence rates were similar (Weissmann et al., 1985). In particular, six-months figures showed an overall rate of 4.6% for anxiety disorders among elderly people, again with the majority classified as patients with phobic disorders (3.9%) and many fewer individuals with OCD (0.7%) or PD (0.1%). Additional analyses of the New Haven data indicated that prevalence rates were higher among homebound elderly people (that is, those confined to homes, beds, or chairs) relative to community residents with more freedom of movement, although these differences may have been related to poorer physical health status among the homebound individuals (Bruce & McNamara, 1992).

Even though the ECA data suggested that anxiety disorders pose a significant mental health problem for elderly people, it is important to note that these figures may have underestimated the percentage of older adults with significant anxiety problems. First, many individuals in this age group tend to underreport or deny psychological symptoms (Lasoski; 1986; Oxman, Barrett, Barrett, & Gerber, 1987). Second, prevalence figures were based on interviews with individuals residing in the community, and it has been demonstrated that rates of anxiety disorders may be much higher among institutionalized elderly people (Bland et al., 1988). Given the significant percentage of elders who reside in institutionalized settings, prevalence figures may seriously underrepresent the scope of anxiety disorders in older populations. Finally, Wave 1 of the survey, which produced the overall 5.5% rate, failed to consider prevalence of post-traumatic stress disorder (PTSD) and generalized anxiety disorder (GAD). GAD was excluded because it had not been recognized as a distinct psychiatric disorder at the time (American Psychiatric Association, 1980). Wave 2 of the study, however, which occurred approximately one year later, queried a subset of the original participants about the symptoms of PTSD and GAD. Only total population estimates for PTSD have been published (Helzer, Robins, & McEvoy, 1987), but six-month and lifetime prevalence rates of 1.9% and 4.6% were noted for GAD in the elderly (Blazer, George, & Hughes, 1991). These rates, although striking as they are presented, also may have underestimated the true prevalence of GAD given that hierarchical diagnostic criteria required exclusion of GAD if any other *Diagnostic and statistical manual of mental disorders* (*3rd ed.*) (*DSM-III*) diagnosis was present. As such, all individuals with diagnoses of major depression or PD, for example, who may also have met criteria for GAD, were not included in the published prevalence rates.

In addition to the data provided by the ECA study, at least seven other random sample community surveys from the US, Canada, and the UK have provided prevalence figures for anxiety problems in older adults (defined here as age 60 years or older; see review by Flint, 1994). Some of these studies surveyed all adults over age 18 but reported separate prevalence figures for older and younger groups, while others examined anxiety only in elderly samples. Across the studies, overall prevalence rates for anxiety disorders ranged from 0.7% to 18.6%. Figures presented separately for specific groups of disorders varied as follows: phobic disorders, 0.0%–10.0%; GAD, 0.7%–7.1%; OCD, 0.0%–1.5%; and PD, 0.1%–1.0% (Flint, 1994). These data generally are consistent with ECA findings that phobias and GAD are most common, although specific figures varied widely given the range of survey methods, case definitions, and diagnostic procedures used to establish diagnoses. For example, some diagnoses were based on self-report measures and others on semistructured clinical interviews. Some studies utilized widely accepted standards for case definition, while others relied on more idiosyncratic diagnostic criteria. In light of these methodological variations, ECA data probably represent the best figures currently available to estimate the prevalence of anxiety disorders in elderly people, despite criticisms that have been leveled at ECA methodology including variations in interview procedures at different sites, the use of lay interviewers rather than trained clinicians, and low sensitivity for diagnostic procedures (Beidel & Turner, 1991; McNally, 1994).

7.08.2.2 Anxiety Symptoms

Another collection of studies has addressed the prevalence of distressing anxiety symptoms in elderly people rather than anxiety disorder diagnoses *per se*. These reports have assessed the frequency and/or severity of symptoms using standardized self-report inventories such as the Hopkins Symptom Checklist (Derogatis, Lipman, Rickels, Uhlenhuth, & Covi, 1973) and the State-Trait Anxiety Inventory (Spielberger, Gorsuch, & Lushene, 1970). In these surveys, cut-off scores based on standard deviations from mean scores in normal and psychiatric samples of older adults were established to define cases of elevated anxiety. This type of methodology has suggested that up to 20% of elderly people in the community report significant levels of anxiety (Feinsen & Thoits, 1986; Himmelfarb & Murrell, 1984). Significant anxiety has also been reported for 8–11% of elders assessed in primary care settings in both the US (Oxman et al., 1987) and Hong Kong (Wong & Pan, 1994). When relevant comparisons have been made, patterns again fail to confirm the notion of increasing anxiety over the life span given lower prevalence of distressing anxiety in older than younger adults (Feinsen & Thoits, 1986; Oxman et al., 1987). Although these figures disallow differential diagnosis that would separate anxiety symptoms resulting from various medical and/or psychiatric conditions (see Section 7.08.4), they nonetheless confirm that a substantial number of elders report distressing anxiety symptoms.

7.08.3 ONSET AND ASSOCIATED RISK FACTORS

7.08.3.1 Age of Onset

It has been suggested from the younger adult literature that age of onset for anxiety disorders may be based at least to some degree on developmental stage (Beidel & Turner, 1991). For example, the onset of specific phobias seems to mirror the progression of developmentally appropriate normal fears through childhood; that is, animal phobias are often first noticed between the ages of four and seven, when animal fears are common (Marks & Gelder, 1996; Ost, 1987), and phobias of natural disasters and health-related situations frequently begin among older elementary school children at the ages when these fears are commonly reported (Barrios, Hartmann, & Shigetomi, 1981). Likewise, the age of onset for social phobia is typically in early to late adolescence when the establishment of social relationships is a critical developmental task (Beidel & Turner, 1991). These patterns suggest that some phobias reported by older adults may represent fears which originated in earlier developmental stages and continued through later adulthood, while others may have developed more recently from concerns that are developmentally appropriate for older adults, for example, fears of falling (Downton & Andrews, 1990). In fact, available data regarding age of onset for phobias in elderly people are mixed, suggesting the possibility of varying periods of onset for different fears. In a British survey of older adults, Lindesay (1991) reported that specific phobias generally had their onset during childhood, a finding that is consistent with data from the younger adult literature (Thyer, Parrish, Curtis, Nesse, & Cameron, 1985). Alternatively, data from the the US ECA study implied that many phobias reported by older adults were of recent onset (Eaton et al., 1989). Similarly, Lindesay reported that agoraphobic fears (e.g., of enclosed places crowds, public transportation, going away from home) among elderly people most often were of recent onset. However, many of these "agoraphobic" fears began after an episode of physical illness or trauma. As such, the fears may have represented realistic or excessive fears of physical limitations rather than anticipation of panic, suggesting that a diagnosis of specific phobia might have been more appropriate for consideration than agoraphobia (see McNally (1994) for a discussion of this diagnostic issue in younger adults). In addition, a high incidence of depression in Lindesay's sample suggested that "agoraphobic" fears may have been associated with a social withdrawal characteristic of a depressive clinical picture (Flint, 1994).

In light of these inconsistent findings and important differential diagnosis issues, as well as the influential role played by developmental stages in the origin of phobias, further investigation is needed to understand patterns of onset for different types of phobias reported by elderly people. In this area, the important differentiation of realistic versus excessive fear is central, particularly given developmentally appropriate fears that may be characteristic of normal aging.

The age of onset for GAD among elderly people appears to have a bimodal distribution. In Wave 2 of the US ECA study, 39% of participants reported duration of GAD for 21 years or more (Blazer et al., 1991). For these individuals, GAD may have been conceptualized best as a personality disturbance rather than an Axis I disorder, a perspective that has received some attention in the literature of the 1990s (Sanderson & Wetzler, 1991). For another 52% of participants, the onset of GAD was reported within five years of the interview. For this subset of older adults, GAD may have begun as a reaction to stressful life events, a pattern that has been documented in both younger and older adults (Blazer, Hughes, & George, 1987; Ganzini, McFarland, & Culter, 1990). In particular, younger adult men and women interviewed in Wave 2 of the ECA survey experienced a threefold increase in risk for GAD in the year following one or more unexpected, negative, and important life events (Blazer et al., 1987). In a separate sample of older adults, an increased incidence of GAD was reported during the 20 months following a catastrophic financial loss (Ganzini et al., 1990). In this sample, 27% of participants reported symptoms meeting criteria for GAD during the postloss period relative to 10% of elders in a control sample during this same time.

A bimodal pattern of onset for GAD was also reported in a sample of older adults recruited for participation in a treatment study (Beck, Stanley, & Zebb, 1996a). A comparison of clinical features (e.g., anxiety, depression, specific fears) in patients with onset of GAD in childhood (before age 15) and those reporting onset in middle adulthood (after age 39) revealed very few differences. The impact of age of onset on treatment response was not studied, however, given inadequate sample sizes.

Given that prevalence rates for PD and OCD in older adults are quite low, few data are available to address the onset of these syndromes. Although ECA data indicated that neither of these disorders typically began in older age (Eaton et al., 1989), a retrospective chart review of 51 elderly clinic patients with panic disorder revealed that over half reported onset at age 60 years or later (Raj, Covea, & Dagon, 1993). Related case reports have also suggested that panic disorder may begin in later life (Luchins & Rose, 1989; Sheikh, King, & Taylor, 1991). However, conclusions about time and mode of onset for PD and OCD will require greater study.

The potential role of stressful life events in the development of anxiety in later life has already been noted (Ganzini et al., 1990). It has also been demonstrated in studies of Holocaust survivors and World War Two prisoners of war that stress-related symptoms of PTSD can persist into old age (Kluznick, Speed, Van Valkenberg, & Magraw, 1986; Kuch & Cox, 1992). However, no data are available regarding onset of PTSD in elderly people. Given the number of traumatic life events that can occur for older adults (e.g., elder abuse, muggings, motor vehicle accidents), onset of PTSD symptoms in later life is of significant interest and importance. Relevant to this issue are published findings suggesting that prior experience with trauma can serve to "inoculate" older adults against the anxiety-related effects of natural disasters (Norris & Murrell, 1988). The more general role of prior stress as a buffer against the development of PTSD in late life will need to be considered.

7.08.3.2 Associated Risk Factors

7.08.3.2.1 Gender

As has been shown repeatedly among younger adults, ECA data demonstrated that elderly women are at greater risk of experiencing anxiety disorders than elderly men, with a ratio of approximately 2:1 among adults over age 65 (Regier et al., 1988; Regier et al., 1990; Weissman et al., 1985). In a similar Canadian survey (Bland et al., 1988), older women residing in the community were 1.5 times more likely to be diagnosed with an anxiety disorder than men in the same age group. In an institutionalized subgroup of participants surveyed for this study, women were five times as likely to be assigned an anxiety disorder diagnosis as men. However, figures from both of these studies failed to address the prevalence and/or gender distribution of GAD. Two studies relevant to this issue have suggested that elderly women are approximately two to nine times more likely than elderly men to meet criteria for this disorder (Flint, 1994). In Wave 2 of the ECA survey, prevalence rates for GAD within gender were presented separately for black and nonblack participants (Blazer et al., 1991). These figures indicated that elderly black women were 12 times more likely to be assigned a diagnosis of GAD than black men in the same age group. Nonblack elderly women also were more likely to be diagnosed with GAD than their nonblack male counterparts, with a ratio of 4:1.

With regard to the prevalence of notable anxiety symptoms instead of disorders, women have also been identified more often than men to have significant anxiety according to pre-established cutoff scores on standardized self-report instruments (Himmelfarb & Murrell, 1984). Similarly, elderly women reported greater overall fearfulness than elderly men on a standardized measure of specific fears (Liddell, Lockes & Burman, 1991). Thus, epidemiological data overall indicate that women are at greater risk of experiencing problematic anxiety than men among the older adult population.

7.08.3.2.2 Ethnicity

Another potential risk factor for the experience of anxiety in elderly people is ethnicity, although the impact of this variable has been understudied. In the ECA survey, problems with sampling strategies for some minority groups were noted across all age groups (Beidel & Turner, 1991), making it difficult to draw even general conclusions from these data. Moreover, very few ECA data relevant to ethnicity have been provided separately by age. Among the elderly people interviewed through the New Haven site, Weissman et al. (1985) noted that rates of cognitive impairment were higher in blacks than whites, although other *DSM-III* disorders were less prevalent among blacks, relative to whites. However, no data were presented regarding the distribution of anxiety disorders among these groups. In Wave 2 of the survey, prevalence rates for GAD in elderly people were presented by both ethnicity and gender, as noted earlier, with figures suggesting the highest rate among black women (3.7%). Rates for the other groups were as follows: nonblack women (2.7%), black men (0.3%), and nonblack men (0.7%).

In studies examining prevalence rates for anxiety symptoms rather than disorders, nonsignificant correlations between ethnicity and anxiety severity have been reported (Feinson & Thoits, 1986; Himmelfarb & Murrell, 1984). However, in one of these reports, minority groups were underrepresented (Feinson & Thoits, 1986), and in the other, the ethnic distribution of the sample was unspecified (Himmelfarb & Murrell, 1984). Given the very limited data available to address this issue, as well as significant methodological problems evident in the reports that are accessible, the potential role of ethnicity as a risk factor for the experience of anxiety in later life is unclear and requires future study.

7.08.3.2.3 Other risk factors

Other potential risk factors for the experience of anxiety in elderly people relate to marital status, income, and level of education. In particular, fewer anxiety symptoms have been reported by married older adults relative to unmarried older persons, including all individuals not married at the time of assessment (Feinsen & Thoits, 1986). A more complicated interaction between marital status and gender was reported in another study, with highest levels of anxiety occurring among never-married men and the least amount of anxiety within a group of never-married women (Himmelfarb & Murrell, 1984). Significant negative correlations have also been noted between income and anxiety among the elderly (Feinsen & Thoits, 1986; Himmelfarb & Murrell, 1984; Liddell et al., 1991), and in some reports, between level of education and anxiety severity (Himmelfarb & Murrell, 1984; Liddell et al., 1991). In general, these patterns are similar to those reported in younger adults with anxiety disorders (Regier et al., 1990).

7.08.4 PSYCHOPATHOLOGY AND DIFFERENTIAL DIAGNOSIS

Significant advances have been made in understanding the nature and experience of anxiety in younger adults (see Barlow, 1988; Beidel & Turner, 1991; Rapee & Barlow, 1991 for reviews of this literature). However, whether this knowledge applies directly to the experience of anxiety among elderly people is unknown. Of crucial importance to this issue are descriptions of the specific nature of anxiety in older adults with and without psychiatric disorders, the relationship between anxiety and medical problems common in older adults, and the overlap between anxiety and sleep disturbance, depression, and cognitive impairment, in particular, memory. These issues are reviewed here.

7.08.4.1 Nature of Anxiety

A small body of literature has begun to address potential differences in the experience of anxiety across the life span. As noted earlier, the prevalence of anxiety disorders seems to decrease with age, but also of interest are potential differences in the qualitative experience of anxiety from younger to older adulthood. In one relevant empirical examination, Lawton, Kleban, and Dean (1993) examined potential differences in the factor structure and prevalence of affect across three age groups: younger adults (ages 18–30), middle-aged adults (ages 31–59), and older adults (age 60 and over). Although a six-factor structure was evident for each group in initial exploratory analyses, subsequent confirmatory analyses revealed differences in the loading sizes, factor correlations, and residual correlations across the three groups. The primary differences occurred between younger and older adults with regard to factors assessing positive affect and depression, but differences between these two groups were also evident on the anxiety-guilt factor. In particular, affect terms assessing guilt (e.g., ashamed, guilty, worried, blamed) were more salient to this factor for younger adults than for the older group. As suggested by the authors, this difference may indicate that older adults grew up before "guilt became fashionable" (p. 174). Consequently, they may experience anxiety more directly than younger adults who make cognitive connections between anxiety and guilt (Lawton et al., 1993). Other analyses revealed that older adults reported less of almost every negative emotional state, including anxiety, than participants in the other two groups. Fewer differences between groups were evident with regard to the experience of positive affect. These data suggest that affect terms may have different meanings across the life span and that the experience of anxiety may vary in important ways with age. As such, theoretical and empirical knowledge regarding the experience of anxiety among younger adults cannot be extrapolated directly to an older population.

Another group of studies has addressed the nature of fears and worries among older adults living in the community. As noted earlier, a developmental examination of normal fears is needed as a baseline against which to understand the experience of problematic anxiety. For older adults, as with individuals in any other age group, it is necessary to differentiate maladaptive anxiety from realistic fears that accompany a particular developmental stage, in this case, aging. It is also important, however, for practitioners not to overattribute anxiety and fears in elderly people to the normal aging process and in so doing, overlook or ignore treatable psychological symptoms (Weiss, 1994). In either case, the experience of anxiety as it accompanies the normal aging process needs to be understood clearly.

The majority of work addressing the nature of normal fears among elderly people has focused on worry, probably because generalized anxiety is one of the most common forms of anxiety in this age group (Blazer et al., 1991). In one community survey of adults ages 25–64, Person and Borkovec (1995) classified participants' worries or concerns into five categories: family–home–interpersonal, illness–health–injury, work–school, finances, and miscellaneous. Comparisons of worries reported by younger (age 25–64) and older (age 65 and over) adults revealed that elderly people worried most about health and least about work, whereas younger adults were most concerned about family and finances. These data suggested that worry content across age groups was representative of changing life circumstances. Similar findings were reported in another community survey of worries in younger and older adults (Powers, Wisocki, & Whitbourne, 1992). In particular, the elderly reported few worries overall, with significantly fewer worries about social events and financial issues than a college-age comparison group. Older adults worried most about health, although scores in this domain were not significantly different from the younger sample.

In an assessment study with 94 older adults characterized via semistructured interview to be free of any psychiatric diagnoses, scores on standardized self-report measures of worry, state and trait anxiety, specific fears, and obsessive-compulsive symptoms were significantly lower than normal mean scores reported in other samples of younger adults (Stanley, Beck, & Zebb, 1996). These data accentuate the need for age-appropriate norms to interpret scores on self-report measures of anxiety symptoms and are consistent with prior findings suggesting that severity of anxiety seems to decrease with age.

The fact that older age is not necessarily associated with increasing anxiety should not detract from the impact that problematic anxiety can have in this population. In one of the first studies to examine the clinical characteristics of anxiety disorders in elderly people, 44 older adults with GAD (diagnosed according to semistructured interview and *DSM-III-R* criteria) were compared with a sample free of psychiatric diagnoses who were equivalent with regard to age, gender, level of education, and ethnicity (Beck et al., 1996a). Analyses revealed that GAD was associated with increased levels of worry, anxiety, social fears, and depression, with scores on these measures comparable to younger samples of GAD patients. Similarly, Raj et al. (1993) reported that clinical characteristics of a group of elderly patients with PD were similar to those reported in younger samples with the same diagnosis. As such, although the overall severity and frequency of fears and worries may decrease over the life span, anxiety disorders appear to be associated with similar clinical features regardless of age. However, additional data with groups of elderly patients meeting criteria for various anxiety disorders are needed to replicate and expand these findings.

7.08.4.2 Anxiety and Medical Problems

The overlap between medical and psychological problems is a highly salient issue for practitioners working with older adults. In fact, it has been suggested that these two areas are so closely interwoven that treatment of mental health problems is impossible without knowledge of medical illnesses common among the elderly (Frazer, 1995). As noted by Frazer, the relationship between physical and psychological symptoms or disorders can occur for at least three reasons: medical illnesses can mimic and/or cause psychological difficulties, the two types of symptoms can coexist, and psychological disturbance can potentially leave one vulnerable for development of physical difficulties. Katz (1996), in a 1995 presidential address to the American Association for Geriatric Psychiatry, noted that the significant degree of interrelatedness between psychological and medical difficulties among elderly people should serve a central role in the development of public policy and the design of health care services for the elderly. In this domain, a reasonable amount of attention has focused on the comorbidity between medical disease and depression (Katz, 1996), but less work has addressed the relationship between physical illness and anxiety.

It is of particular importance to consider the overlap of anxiety and medical disease, given that older adults often attribute anxiety-related symptoms such as agitation, fears, or aches and pains to physical illness, thereby denying or underreporting psychological difficulties (Gurian & Miner, 1991). Furthermore, a range of medical conditions can create anxiety-like symptoms, in particular, cardiovascular disease, chronic obstructive pulmonary disease, hyperthyroidism, and visual and auditory impairments. (Cohen, 1991). Limited empirical data have addressed the nature of the overlap between physical illness and anxiety, although a few studies have explored the prevalence of anxiety symptoms in samples of older adults presenting to medical clinics or hospitals.

As noted earlier, prevalence rates of 8–11% for anxiety disorders were reported among elderly outpatients (age 55 years and over) in a rural US group practice (Oxman et al., 1987). Case identification in this study was based on symptom checklist scores that were at least two standard deviations above a mean. Given apparent differences in prevalence rates for anxiety in urban and rural settings (Blazer et al., 1991), along with the restricted ability of self-report inventories to identify diagnosable cases, the data from this report are somewhat limited. In another survey of Italian medical inpatients, 40% of adults over age 60 reported moderate to high levels of distress on an anxiety symptom checklist (Magni, Schifano, deDominicis, & Belloni, 1988). Severity of anxiety was not associated with the classification of medical problems as being acute or chronic, but scores on a phobia subscale were significantly higher for patients with central nervous system disturbances than for those with other diseases. Again, although these data provide an interesting pattern of results, conclusions are limited given reliance solely on a self-report symptom checklist to evaluate anxiety.

In two other studies, elderly medical patients were evaluated to examine the relationship between complaints of postural disturbance (dizziness, fear of falling) and anxiety. In one of these, 203 adults age 75 and over were recruited from four general medical practices in Manchester, UK (Downton & Andrews, 1990). In this sample, dizziness and fear of falling were associated with higher levels of anxiety, and symptoms were more severe for participants who had actually experienced a fall within the previous 12 months. It is interesting to note that 42% of the sample reported restricted activity due to fear of falling, a behavioral pattern that requires differentiation from agoraphobic fears reported in older adults (Beck & Stanley, 1997). In another report, 37.5% of 56 older adults (age 60 and over) who presented to a dizziness clinic were diagnosed with at least one *DSM-III-R* Axis I disorder (Sloane, Hartman, & Mitchell, 1994). The most frequent diagnoses in this group were anxiety disorders, depression, and adjustment disorders. Older adults with chronic dizziness also scored significantly higher on a symptom checklist of anxiety than a matched group of healthy adults. In a follow-up study of stroke survivors, prevalence rates of 5% and 19% for anxiety disorders were reported for elderly men and women at four months post-stroke (Burvill et al., 1995). When hierarchical rules for diagnosing *DSM-III* disorders were suspended, rates were 12% and 28% for men and women, respectively. Participants with anxiety disorders at the time of stroke were identified via retrospective interview. When these individuals were excluded, prevalence rates for men and women were 9% and 20%, figures that far outweigh general population estimates for older adults.

These data suggest that elderly patients presenting for medical treatment frequently have disturbing symptoms of anxiety. As such, it is important for medical practitioners to be aware of the signs and symptoms of anxiety and to provide appropriate treatment or referrals when needed. Likewise, it is important for mental health care providers to be cognizant of medical causes or correlates of anxiety (Stanley & Beck, in press). In this latter domain, epidemiological data from a British survey documented that older adults with phobic disorders reported significantly more physical symptoms than control participants (Lindesay, 1991). In particular, adults with phobic disorders more frequently reported the experience of palpitations, dyspnea, dysphagia, abdominal pain, bowel problems, giddiness, tinnitus, and joint swelling within the three months prior to interview. In another community survey, a strong positive correlation ($r=0.60$) was observed between severity of anxiety and physical health problems (Himmelfarb & Murrell, 1984). Given a reported low correlation between age and physical health, however, the authors concluded that the observed relationship between anxiety and physical condition was not mediated only by age. Multivariate examination of this issue appears warranted, as bivariate correlations do not reveal complex patterns of interrelationships among variables. In a study of institutionalized elders living in nursing homes or congregate housing, significant associations were also observed between anxiety and physical health, with more anxious residents reporting more severe renal problems and other gastrointestinal and urninary difficulties (Parmelee, Katz, & Lawton, 1992).

Taken together, these data strongly support the importance of considering the overlap between anxiety symptoms and medical health problems. To determine appropriate diagnoses and treatment approaches, close attention to both of these areas is paramount, with careful focus on differential diagnosis issues. It seems clear that any evaluation of older adults presenting for either psychological or medical help should include detailed assessments in both domains.

7.08.4.3 Anxiety and Sleep Disturbance

Sleep disturbance, in particular insomnia, is a frequent problem among older adults (Engle-Friedman & Bootzin, 1991) and in fact, is the topic of Chapter 14, this volume. Of interest here, however, is the potential overlap between sleep disturbance and anxiety. Sleep difficulties in elderly people are often viewed as part of the normal aging process and thereby overlooked or underdiagnosed, as are many other symptoms reported frequently in this group (Morin & Gramling, 1989). However, sleep disturbance can lead to changes in mood and conversely, stress and psychopathology can create disruptions in normal sleep patterns (Engle-Friedman & Bootzin, 1991). Thus, an examination of the overlap between sleep difficulties and anxiety is of relevance.

Insomnia has been associated with increases in a variety of self-reported psychological symptoms, including introversion, anxiety, neuroticism, and depression (Engle-Friedman & Bootzin, 1991). When relevant comparisons of older and younger adults have been undertaken, elders reporting sleep disturbance have endorsed fewer symptoms of anxiety, depression, and other psychopathology than younger individuals with similar difficulties (Bliwise, Bliwise, & Dement, 1985; Roehrs, Lineback, Zorick, & Roth, 1982; Roehrs, Zorick, Sicklesteel, Wittig, & Roth, 1983). Morin and Gramling (1989) suggested a number of possible explanations for this pattern, including differences in typical problematic sleep patterns across the two groups (i.e., older adults more often report trouble maintaining rather than initiating sleep) and the tendency of older adults to focus on physical rather than psychological symptoms. Nonetheless, at least two recent studies have demonstrated a significant relationship between sleep difficulties and increased anxiety among the elderly.

In the first of these, Morin and Gramling (1989) assessed 42 adults age 60 and over who responded to media advertisements for participants with chronic sleep difficulties. These individuals were compared on a variety of sleep and mood measures with a control group of 30 individuals matched for age, gender, education, and marital status. Results demonstrated increased levels of anxiety and depression in the self-reported insomniac group relative to the comparison group without sleep difficulties. However, scores on mood measures within the poor sleeper group were not in the pathological range, suggesting to the authors that sleep disturbance alone may not be a good indicator of psychological problems among elderly people. In a more recent study, Friedman, Brooks, Bliwise, and Yesavage (1993) extended these findings by including an objective measure of sleep, in particular a wrist actigraph. Twenty-seven older community volunteers with sleep complaints were assessed on measures of state and trait anxiety and depression. They were also asked to complete daily sleep logs for a period of two weeks and to wear a wrist actigraph continuously for a period of three days. Results demonstrated no correlation between state anxiety and any measure of sleep. However, trait anxiety correlated positively with two self-reported sleep measures: amount of time spent awake after first falling asleep, and total time spent in bed. Trait anxiety also correlated in a significant positive way with total sleep time as determined by the actigraph. The positive correlation between anxiety and total sleep time was unexpected, although the authors noted that the actigraph may have overestimated sleep time for participants who spent a lot of time lying awake and motionless in bed. They also suggested that more anxious adults may have perceived their sleep to be worse than it actually was.

In addition to the mixed data regarding anxiety in older adults with sleep complaints, it is of interest to note that some treatment studies for sleep disorders in elderly people have examined the impact of relaxation treatment (Friedman, Bliwise, Yesavage, & Salom, 1991) or have included relaxation as part of a multicomponent treatment package (Morin, Colecchi, Ling, & Sood, 1995). The impact of relaxation for reducing anxiety is well-known, although studies addressing the utility of these interventions for sleep disturbance failed to include measures of anxiety that might have addressed the impact of treatment on coexistent psychological symptoms. In another study of psychosocial treatment for insomnia that omitted an anxiety-reduction component (Morin, Kowatch, Barry, & Walton, 1993), no impact of treatment on anxiety was noted. However, given the apparent overlap between symptoms of anxiety and sleep difficulties for at least some patients, it will be of interest for future treatment studies of both anxiety and insomnia to examine more regularly transfer effects to the nontarget set of symptoms.

7.08.4.4 Anxiety and Depression

The overlap between anxiety and depression is an issue of longstanding importance within psychology and psychiatry given the high rates of coexistence for these conditions regularly reported among younger adults (Cloninger, 1990; Copp, Schwiderski, & Robinson, 1990; Feldman, 1993). In fact, six-month prevalence data from the ECA survey documented that one-fifth of individuals with an anxiety disorder also had symptoms that met criteria for an affective disorder (Regier et al., 1990). Conversely, one-third of those assigned an affective disorder diagnosis also were given at least one anxiety disorder diagnosis (Regier et al., 1990). Given these high rates of coexistence, further understanding of the nature of this overlap is warranted among elderly people.

ECA data regarding the coexistence of anxiety and affective disorders were not presented separately for the elderly. Nonetheless, recent reviews have highlighted the significant overlap between these sets of diagnoses and symptoms in this segment of the population (Alexopoulos, 1991; Flint, 1994). With regard to data addressing coexistence of assigned diagnoses, it has been reported that over 90% of older adults from the community who reported symptoms appropriate for a diagnosis of GAD also met criteria for depression (Lindesay, Briggs, & Murphy, 1989). In this same community sample, almost 40% of individuals with a phobia diagnosis were also assigned a diagnosis of depression according to the *International classification of disease* (*8th ed.*) (*ICD-8*) criteria assessed via semi-structured interview. In another study conducted via retrospective chart review (Raj et al., 1993), 45% of elderly clinic patients with PD diagnosed according to *DSM-III-R* also met criteria for coexistent major depression. In an examination of 44 older adults with a principal *DSM-III-R* diagnosis of GAD (Beck et al., 1996a), approximately 15% met criteria for a coexistent affective disorder. When older adults with affective disorders have been evaluated, over one-third have met criteria for a coexistent anxiety disorder diagnosis (Alexopoulos, 1991). Thus, rates of overlap between anxiety and affective disorders among the elderly are high.

Other reports have addressed the degree of overlap between symptoms of anxiety and depression, rather than prevalence of coexistent disorders *per se*. In these studies, significant positive associations between symptoms of anxiety and depression have been observed in community samples of older adults (Lindesay et al., 1989; Ben-Arie, Swartz, & Dickman, 1987), institutionalized elderly people (Parmelee et al., 1992), and older clinic patients (Alexopoulos, 1991). In the authors' own investigation of older adults with GAD, higher levels of depressive symptoms were also evident relative to a matched control sample (Beck et al., 1996a).

In a longitudinal study of 1070 older adults from the community, 702 of whom were interviewed twice over a three-year interval, Larkin et al (1992) reported some covariance between anxiety and depressive symptoms assessed in the context of "neurotic" conditions. These data highlight further the significant overlap between anxiety and depression among the elderly, and may even be interpreted to support some indistinguishability among these two sets of symptoms (Beck & Stanley, 1997). However, data reviewed below attest to the ability of clinicians to differentiate and diagnose both types of disorders reliably among elderly samples (see Section 7.08.5).

7.08.4.5 Anxiety and Cognitive Impairment

Normal age-related changes in cognitive functioning have been studied extensively (see Chapter 2, this volume), and a relatively large body of work has examined the impact of depression on cognitive performance among elderly people (see Chapters 9 and 10, this volume). Results of this latter research have demonstrated moderate relationships between depression and cognitive impairment that are influenced by sample characteristics and the measures selected to evaluate cognitive function (Burt, Zembar, & Niederehe, 1995; Poon, 1992). Less work has examined the overlap between anxiety and cognitive functioning, and results of available studies are mixed and limited by a number of methodological problems. In particular, wide ranges of both anxiety and cognitive measures have been used, limiting the ability to generalize findings across studies. In addition, the majority of studies have been conducted with community volunteers recruited for participation in studies of memory. No studies to date have examined cognitive function among older adults who report significant anxiety symptoms or who meet diagnostic criteria for anxiety disorders. Nonetheless, among older adult volunteers, some relationships have been demonstrated between increased anxiety and decreased cognitive performance, most often related to memory.

In one early report, 67 women volunteers over age 65 were administered measures of anxiety, verbal and nonverbal memory, and self-reported memory complaints in a single testing session (West, Boatwright, & Schleser, 1984). Results demonstrated significant negative correlations between state anxiety and measures of nonverbal memory (recall for sequences of related or unrelated numbers), although no similar relationship was demonstrated between anxiety and memory for lists of related or unrelated words. Higher state anxiety was also related to increased memory complaints, although life satisfaction was a stronger predictor of perceived memory abilities.

In another study of community volunteers, ages 60–79, significant negative correlations were noted between state anxiety and cognitive performance measured by a Piagetian problem-solving task and the Wechsler Adult Intelligence Scale Similarities subtest (LaRue & D'Elia, 1985). In this report, correlations between anxiety and cognitive function were stronger among younger adults ($r = 0.24$–0.46), ages 40–59, relative to older adults ($r = 0.09$–0.29). Hill and Vandervoort (1992) reported a significant negative association between state anxiety and performance on a verbal memory task for a group of 74 older adult volunteers, age 60 years and older. However, it is important to note that the measure of anxiety in this study was administered after participants were given feedback about their cognitive performance. As such, feedback that performance had been poorer than expected might have created elevated levels of anxiety. In another comparison, significant negative correlations were observed between measures of verbal recall and anxiety, depression, and social withdrawal for older adult volunteers, ages 60–78 (Deptula, Singh, & Pomara, 1993). In this group, ratings of social withdrawal accounted for a significantly larger proportion of the variance in memory scores than both anxiety and depression. In a younger group of adults assessed in the same study (ages 19–35), no significant relationships were observed between any measure of affect and memory.

In addition to these studies demonstrating significant, albeit moderate, relationships between anxiety and cognitive performance, another small set of reports has examined the impact of anxiety reduction treatment on memory. In the earliest of these, 26 older adult volunteers, ages 59–85, were recruited for a memory improvement study (Yesavage, Rose, & Spiegel, 1982). Participants with evidence of dementia or significant depression were excluded, and four weekly sessions of relaxation training were provided. Anxiety measures were taken at pretreatment, and verbal recall was measured before and after relaxation induction during session three. Results revealed significant positive correlations between two measures of anxiety and improvement in recall following relaxation. In other words, participants with increased anxiety before treatment improved more on the recall task following relaxation. In a second study, Yesavage and Jacob (1984) provided training in both relaxation and mnemonic procedures for a group of 25 older adults, ages 61–82. Results revealed improvement in memory following the combined intervention and significant negative correlations between anxiety and recall at post-treatment.

In general, this small body of literature suggests some potentially important overlap between anxiety and cognitive function. However, further studies are needed to examine cognitive performance in older adults with well-diagnosed anxiety disorders relative to carefully selected control participants. In addition, broad-based and well-standardized measures of both anxiety and cognitive function need to be used.

7.08.5 MEASUREMENT

Severity of anxiety can be measured in a variety of ways, including clinician ratings, standardized self-report instruments, behavioral observation, and psychophysiological recording. Among younger adults, strategies for the evaluation of anxiety within each of these domains have received extensive study, and many well-established measures are currently available (Nietzel, Bernstein, & Russell, 1988). However, as has been suggested elsewhere (Hersen & Van Hasselt, 1992, Hersen, Van Hasselt, & Goreczny, 1993), the same type of work is needed to establish the utility of a range of anxiety measures for use with elderly people. In fact, the development of psychometrically sound assessment tools for evaluating anxiety in this population will be the cornerstone of future research examining the psychopathology and treatment of older anxious adults.

At least two general approaches have been taken in the initial development of anxiety measures for older adults. In one of these, the utility of measures developed with younger samples has been assessed with older participants. This approach is economical and allows for direct comparisons of clinical features in younger and older groups. However, such a strategy may fail to take into account phenomenological features of anxiety that are particularly salient for older adults (e.g., worries about health), and may overlook potentially important discriminations between anxiety and related difficulties (e.g., medical problems, depression) (Hersen et al., 1993; Sheikh,1991). Given these limitations, an alternative approach involves the development of unique measures of anxiety for use among the elderly. This method is more costly in terms of time and expense, but it allows for more specialized assessment. Both of these strategies have been used to produce a small amount of work focused on the development of assessment technques for measuring anxiety in older adults.

7.08.5.1 Clinician-rated Measures

Clinician-rated instruments have been used routinely among younger adults to diagnose anxiety disorders and evaluate the severity of anxiety symptoms. With regard to establishing anxiety disorder diagnoses, recent data have suggested that two semistructured interviews used routinely among younger adults can also be used reliably in elderly samples. First, the Anxiety Disorders Interview Schedule-Revised (ADIS-R; DiNardo, Moras, Barlow, Rapee, & Brown, 1993) was used by the authors and colleagues in a set of studies designed to examine the nature and treatment of GAD among adults ages 55 and over (Beck et al., 1995, 1996a; Stanley, Beck, & Glassco, 1996; Stanley et al., 1996). Estimates of interrater reliability for use of this measure indicated 100% agreement for principal diagnoses of *DSM-III-R* GAD (although this may have been due at least in part to extensive telephone screening of participants prior to ADIS-R administration), as well as perfect agreement for coexistent diagnoses of social phobia, simple phobia, and panic disorder ($\kappa = 1.00$). Moderate reliability was noted for the diagnosis of major depression ($\kappa = 0.58$). Although these data were obtained with only 28% of the total sample ($n = 14$ of 50), the figures nonetheless suggest that the ADIS-R can be a useful tool for the diagnosis of anxiety and affective disorders among older samples. Future studies will need to address the utility of the ADIS-IV (Brown, DiNardo, & Barlow,1994), which was recently created to conform with *DSM-IV* criteria (American Psychiatric Association, 1994).

Another set of studies examined the utility of the structured clinical interview for *DSM-III-R* (SCID, Spitzer, Williams, Gibbon, & First, 1988) among older adults (Segal, Hersen, Van Hasselt, Kabacoff, & Roth, 1993; Segal, Kabacoff, Hersen, Van Hasselt, & Ryan, 1995). This interview covers a broader range of potential psychiatric disorders than the ADIS, and data have supported its use for the diagnosis of anxiety, affective, and somatoform disorders in older samples. In particular, the SCID was administered to two sets of adults ages 55 years and older, with all interviews reviewed by a second clinician to evaluate interrater agreement for any diagnostic category with a base rate over 10%. Kappa coefficients indicated adequate agreement for the broad categories of anxiety disorders (0.73–0.77) and somatoform disorders (0.84–1.00), as well as the more specific diagnoses of major depression (0.70–0.79) and panic disorder (0.80). These data suggest that the SCID can also be useful for the diagnosis of anxiety disorders among the elderly. It is important to note, however, that all data examining the reliability of the ADIS and SCID have utilized videotaped interviews which may heighten interrater agreement given that reliability raters are able to hear the interviewer's questions at key decision points of the interview. In this regard, future studies should address the reliability of the interviews when administered separately by two different clinicians.

Other clinician-rated instruments focus on the severity of anxiety symptoms, irrespective of psychiatric diagnosis. The most well-known of these instruments is the Hamilton Anxiety Rating Scale (HARS, Hamilton, 1959), a 14-item measure used routinely in studies of anxiety in younger adults. Although the potential utility of the HARS among the elderly has been questioned due to its emphasis on somatic symptoms (Sheikh, 1991), a report by the authors and colleagues provided support for its use among older adults (Beck, Stanley, & Zebb, 1996b). In particular, interrater agreement for the HARS was adequate among a subgroup of older adults with GAD. Additionally, the instrument successfully discriminated the patient sample from a matched group of normal control participants without psychiatric diagnoses, with near perfect classification. The patient and control groups were both selected based on administration of the ADIS-R, and normative data for the HARS were provided for each. As such, this instrument is a potentially viable measure for evaluating anxiety severity in older adults. However, correlations between the HARS and the Hamilton Rating Scale for Depression (HRSD, Hamilton, 1960) were high (Beck et al, 1996b), and the utility of these measures for discriminating between anxiety and depression among the elderly warrants further study. Revisions in both the HARS and HRSD have been proposed in an attempt to improve internal consistency and discriminant validity (Riskind, Beck, Brown, & Steer, 1987). However, these reconstructed scales continue to share considerable variance among older adults (Beck et al. 1996b), a finding that has also been documented in younger samples (Moras, DiNardo, & Barlow, 1992).

7.08.5.2 Self-report Measures

A wide range of psychometrically sound self-report measures are available to assess anxiety in young and middle-aged adults, although only a small body of literature has examined the utility of these same measures with older samples. Moreover, much of this work is limited due to heterogeneous samples of participants, omission of standardized diagnostic procedures for group assignment, and potentially confounding variables including medication use and poor physical health (Hersen & Van Hasselt, 1992).

The earliest studies attempting to document the utility of standardized anxiety questionnaires among older adults evaluated the psychometric properties of the Spielberger State-Trait Anxiety Inventory (STAI; Spielberger et al., 1970). In an initial report, the STAI was administered along with the STAI for Children (STAIC; Spielberger, Edwards, Lushene, Montouri, & Platzek, 1973) to a group of adults, ages 55–87, who were participating in a mental health gerontology program. (Patterson, O'Sullivan, & Spielberger, 1980). The STAIC was included given that its simpler verbage and format were thought to be appropriate for some individuals who experienced difficulty with the STAI. Results provided support for the convergent and divergent validity of both instruments. Given that the STAI and STAIC were significantly and positively correlated, the authors recommended that these instruments could be used as parallel forms for the evaluation of anxiety in older adults (Patterson et al., 1980). However, the small and heterogeneous nature of the sample, as well as the inclusion of some participants who were heavily medicated, limits these conclusions (Hersen & van Hasselt, 1992). In addition, variations in item content and format between the STAI and STAIC limit the potential utility of these measures as parallel forms.

In another study with the STAI, the trait scale was administered to two large samples of geriatric inpatients and community residents (Himmelfarb & Murrell, 1983). Adequate internal consistency was evident in both groups, and convergent validity was demonstrated by significant correlations between the STAI trait scale and other measures of negative affect and life satisfaction. STAI scores were significantly different between the inpatient and community groups, even when variance accounted for by age, gender, health, and marital status was removed. However, the most potent predictors of group membership were measures of depression and life satisfaction, with the STAI trait scale providing no additional contribution to the differentiation of groups. The implications of these findings for the utility of the STAI in discriminating anxious and nonanxious elders are limited, however, given that the patient group was not selected to represent individuals with primary anxiety difficulties. In fact, both groups were heterogeneous and standardized diagnostic procedures were not used.

More recently, the authors and colleagues investigated the psychometric properties of the STAI in 50 older adults with GAD and a control group of 94 older adults with no diagnosable psychiatric difficulties (Stanley et al., 1996). Participants in both groups were identified based on the ADIS-R, and data provided support for the internal consistency of both STAI subscales in each group. Test–retest reliability, assessed in a subset of the normal control group, was strong for the trait subscale, but only moderate for the state subscale, as expected. Convergent validity for the STAI was evident in the control group, but mixed results in this regard were apparent among participants with GAD, suggesting some degree of independence among different types of anxiety symptoms within this group. In general, although methodological limitations of these reports preclude definitive conclusions, the STAI appears to be a potentially useful measure of anxiety among elderly people.

Other self-report measures that have been examined in samples of older adults include Hopkins Symptom Checklist (SCL-90, Derogatis et al., 1973), the Self-Rating Anxiety Scale (SAS, Zung, 1971), the Penn State Worry Questionnaire (PSWQ, Meyer, Miller, Metzger, & Borkovec, 1990), the Padua Inventory (PI, Sanavio, 1988), and the Fear Questionnaire (FQ, Marks & Mathews, 1979). Data addressing the SCL-90 and SAS are limited to descriptive reports of SCL-90 scores in a group of 178 elderly hospital patients (Magni & De Leo, 1984) and SAS scores for 92 older adults from the community (Zung, 1980). Thus, conclusions about the utility of these measures are tentative at best.

More thorough psychometric data addressing the potential use of the PSWQ, PI, and FQ are available from data collected by the authors and colleagues in their study of the nature and treatment of GAD among the elderly (Beck et al., 1995; Stanley et al., 1996). The PSWQ is a 16-item scale designed to evaluate the tendency to worry, irrespective of worry content; the PI is a 60-item questionnaire that evaluates obsessive-compulsive symptoms; and the FQ is a 15-item instrument measuring severity of specific fears. All of these instruments have strong psychometric properties when used to assess various aspects of anxiety among younger adults. One purpose of the authors' work was to assess whether psychometric characteristics of these measures would be similar in older adult groups. As noted previously, two samples of older adults were selected via diagnostic interview for this set of studies, one characterized by the presence of GAD and the other with no diagnosable psychiatric complaints. Participants with GAD were administered the questionnaires as part of a larger pretreatment battery; normal control participants received financial compensation for completion of the instruments.

In general, results supported the utility of the PSWQ and the PI (Beck et al., 1995; Stanley et al., 1996). In particular, estimates of internal consistency were adequate for both measures in each participant group, with the exception of the PI behavior control subscale in the normal control group. This subscale measures fears of losing control over motor behavior, a symptom that was only seldom endorsed in this group. Thus, a restricted range of scores in the control group probably created subscale instability in this instance. Adequate convergent validity was demonstrated for the PSWQ and the PI in both participant groups. Factor analysis of the PSWQ suggested a two-factor structure in both groups, with one factor assessing a tendency to worry and a second factor estimating the absence of worry (Beck et al., 1995). Similar analyses were not conducted for the PI given inadequate sample sizes (Stanley et al., 1996). The test–retest reliability of the PI, assessed in a subsample of the normal control group, demonstrated that the total score and scores on the contamination and behavior control subscales assessed stable, trait-like features ($r > 0.70$), while scores on the mental control and checking subscales ($r = 0.61$, 0.64) estimated more statelike clinical symptoms. In general, however, these initial data supported the utility of the PSWQ and the PI in anxious and nonanxious elders.

On the other hand, data for the FQ suggested that alternative measures of specific fears should be investigated for use with the elderly (Stanley et al., 1996). In particular, estimates of internal consistency were mixed in both groups of participants, a finding that is unexpected given the construction of the FQ and the stable nature of phobic fear. Test–retest reliablility (as above, assessed in a subgroup of the normal control sample) was poor and suggested the possibility of regression to the mean over a two to four week interval. In addition, the FQ failed to correlate significantly with other measures of anxiety, indicating poor convergent validity. Furthermore, item content was not selected to probe specific fears of particular relevance for the elderly. As such, the FQ does not appear to be a viable measure of specific fears among older adults.

As an alternative to examining the psychometric properties of measures that are well-established for younger groups, at least one measure of anxiety has been developed specifically with older adults in mind. Wisocki and colleagues created the Worry Scale (WS, Wisocki, Handen, & Morse, 1986), a 35-item questionnaire, to assess worries of particular significance for older adults, namely, concerns about financial, health, and social issues. Initial normative data and support for concurrent validity of the WS were provided by Wisocki and colleagues (Powers et al., 1992; Wisocki, 1988; Wisocki et al., 1986). In the authors' own work described above (Stanley et al., 1996), the WS also demonstrated good internal consistency and generally adequate test–retest reliability. The only exception to the latter was poor stability for the health subscale, potentially due to the sensitivity of this measure to real physical complaints which may vary over time. Finally, the WS demonstrated adequate convergent validity. In this regard, the measure seems to hold promise for the evaluation of worry in older adults.

7.08.5.3 Behavioral Observation

Behavioral observation has been described as an essential component for the evaluation of fear and anxiety (Last & Hersen, 1988). Despite the availability of various systematic schemes for behavioral observation of anxiety among younger adults (Nietzel et al., 1988), only case studies have provided any such approaches for the assessment of anxiety in elderly people. In one report, Turner, Hersen, Bellack, and Wells (1979) described a behavioral observation scheme for monitoring ritualistic handwashing and associated symptoms in a 66-year-old woman with OCD. Behavioral observations were made on an inpatient unit by research assistants three times a day, with measures estimating mean time spent washing and percentage of observation periods in which washing occurred. In another case report, Junginger and Ditto (1984) measured the frequency and nature of checking behaviors in a 65-year-old woman receiving inpatient psychiatric treatment for OCD and major depression. However, no standardized approaches for the behavioral observation of anxiety symptoms in older adults have been developed, and the need for further research in this area has been highlighted (Hersen et al., 1993). In particular, reliable systems for the observation of behavior in clinical and naturalistic settings are needed.

7.08.5.4 Psychophysiological Assessment

As noted by Hersen et al., (1993) psychophysiological responses to stress may be expected to change with increasing age. In particular, changes in cardiovascular variables over the life span have been reported, with older anxious adults showing increased cardiovascular reactivity (Hersen et al., 1993). However, hypothesized age-related changes in physiological functioning are not well-documented, and psychophysiological assessment of anxiety is an issue that has yet to be addressed within the older adult literature. Of interest here will be comparisons of baseline arousal in older anxious and nonanxious adults, as well as potentially differential responses to stressors and feared stimuli (Hersen et al., 1993). In general, the inclusion of physiological measures should be considered carefully, as the use of psychophysiological assessment has not always yielded useful information about the nature and treatment of anxiety (Barlow & Maser, 1984).

7.08.6 TREATMENT

7.08.6.1 Utilization of Services

It is well-documented that mental health resources are severely underutilized by the elderly (Arean, 1993; Lasoski, 1986; Smyer & Gatz, 1995). Overall, it appears that only about one-third of older adults in need of mental health care actually see a mental health professional; the other two-thirds either receive no care or obtain services from primary care physicians (Smyer & Gatz, 1995). Low rates of referral for psychiatric or psychological services have also been reported among primary care physicians who treat older adults (Smyer & Gatz, 1995).

More specific data relevant to treatment of anxiety disorders among elderly people are similarly disconcerting. For example, Blazer et al. (1991) reported that only 38% of older adults with GAD indicated use of outpatient mental health services during the year before they were interviewed. Even lower rates of mental health care were reported in the ECA study, with less than 1% of older adults with agoraphobia and only 2% of those with other phobias indicating that they had sought sevices from a mental health professional during the previous six months (Thompson et al., 1988). A larger percentage of elders with phobic disorders reportedly had sought help for mental health problems from other sources (e.g., clergy, general physicians), but rates of help-seeking overall were still significantly lower among older adults than in the group of adults between the ages of 25 and 64 (Thompson et al., 1988).

A number of explanations have been posited to account for these low rates of mental health care among the elderly. First, older adults themselves are reluctant to define their difficulties in terms of psychological problems, and they are often hesitant to seek social services of any kind (Lasoski, 1986; McCarthy, Katz, & Foa, 1991). Additionally, older adults may be fearful of the implications of their symptoms and perceive that mental health services will be of no real benefit (Smyer & Gatz, 1995). Problems in daily living, such as transportation difficulties and financial limitations, may also contribute to low rates of mental health care services sought by the elderly. Second, problems within the health care community can also be identified. For example, relatively few treatment providers with adequate training are available to provide services to older adults, and outreach and/or publicity of services are often limited (Lasoski, 1986; McCarthy et al., 1991). In addition, negative attitudes about the aging process, and perceptions that the signs and symptoms of anxiety are due merely to normal aging and are therefore irreversible, may create a tendency to ignore or misdiagnose mental health problems among elderly people (Smyer & Gatz, 1995; Weiss, 1994).

Despite the low rates of services sought by elders, a growing body of literature has begun to address the efficacy of both pharmacological and psychosocial interventions for anxiety problems. Much of this literature is limited by serious methodological problems, but growing interest in the nature and treatment of anxiety in this population suggests that notable advances in the area will be made in the early years of the twenty-first century.

7.08.6.2 Pharmacological Interventions

Given that much of the mental health care sought by older adults is provided through primary care physicians, (Blazer et al., 1991; McCarthy et al., 1991; Smyer & Gatz, 1995), it is not surprising that treatment for anxiety most often involves the use of medication, usually the benzodiazepines. Among older adults, use of the benzodiazepines occurs far more frequently than in younger samples. (Blazer et al., 1991; Salzman, 1991). Clinical recommendations for the use of benzodiazepines among the elderly, however, are not based on well-controlled treatment trials. Although some data have suggested the utility of a variety of benzodiazepines, all studies available in the late 1990s are limited by serious methodological problems (Cohn, 1984; Salzman, 1991). For example, patients generally were not selected via any systematic diagnostic procedure. As such, generalization of conclusions is limited by the heterogeneous nature of the study samples. Relatedly, patients with anxiety symptoms or disorders were not well-differentiated from participants with anxiety secondary to depression or medical illness, nor was anxiety always distinguished from behavioral agitation associated with cognitive impairment. Finally, the studies varied significantly with regard to outcome criteria, treatment duration, and the use of concommitant medications.

Despite the severe methodological limitations of the outcome literature, recommendations regarding the use of benzodiazepines are fairly consistent, with the suggestion that compounds with short half-lives be used for as brief a duration as possible (Fernandez, Levy, Lachar, & Small, 1995; Markovitz, 1993; Weiss, 1994). Benzodiazepine doses recommended for older adults are also generally lower than those prescribed for younger adults given altered pharmacokinetic properties that lead to increased therapeutic and adverse effects (Lader, 1986). In general, strategies for benzodiazepine use have been recommended based on studies addressing the utility of anxiolytics in younger adults, the pharmacokinetic properties of the medications in nonsymptomatic older samples, and anxiolytic toxicity among the elderly (Salzman, 1991).

Problems with the use of benzodiazepines among the elderly are noted routinely, with some authors even suggesting that psychosocial interventions be considered in conjunction with a pharmacological approach (Lader, 1986; Wengel, Burke, Ranno, & Roccaforte, 1993). Given the increased sensitivity to these medications generally observed in older adults, adverse events of particular concern include cognitive impairment (e.g., amnesia, delayed recall, confusion, disorientation), agitation (which may exacerbate anxiety symptoms), respiratory depression, and psychomotor slowing which may lead to increased rates of falls and hip fractures (Weiss, 1994; Wengel et al., 1993). Increased rates of medical illness among older adults also raise the issue of potentially harmful drug interactions.

Thus, although the benzodiazepines are recommended routinely for the treatment of anxiety among the elderly, the literature upon which clinical recommendations are made is quite limited and the increased risk of potentially serious adverse effects warrants caution in using these compounds. Other medications may be considered as alternatives, although again, the relevant treatment literature is quite limited in scope. For example, clinical recommendations have suggested the use of buspirone as an alternative to benzodiazepines for the treatment of anxiety in older adults, given its apparently equivalent therapeutic effects without significant potential for serious adverse effects, tolerance, or withdrawal (Weiss, 1994). However, the treatment literature has documented the efficacy of buspirone only in a number of open trials (Salzman, 1991), and other more well-controlled research will need to substantiate these clinical claims. Likewise, clinical recommendations have suggested the potential utility of beta blockers and antidepressants for the treatment of anxiety among the elderly (Fernandez et al., 1995; Markowitz, 1993), but these suggestions are based only on literature documenting the efficacy of these compounds in younger anxious adults. Future studies will need to address directly the efficacy of these medications in well-diagnosed samples of older adults.

7.08.6.3 Psychosocial Interventions

The consideration of psychosocial treatments as an adjunct or alternative to the use of medication for the treatment of psychiatric disturbance in the elderly is an important but understudied issue. In general, it has been noted that many of the basic clinical skills useful for the treatment of younger adults are appropriate for therapeutic work with elderly people (Taylor & Hartman Stein, 1995). However, variations in technique or approach are often necessary to address the special needs of an older population. In particular, the importance of assessing both patients' and family members' beliefs about mental health problems and their treatment has been noted, as well as the need to educate both of these groups about the nature of psychosocial treatment (Arean, 1993; Gallagher-Thompson & Thompson, 1995). In addition, differences in learning strategies and sensory function between older and younger adults need to be considered, with recommendations suggesting that therapy with elderly people occur at a slower pace and include increased use of visual and written aids (Gallagher-Thompson & Thompson, 1995; Smyer, Zarit, & Qualls, 1990) Group approaches have also been recommended to reduce cost and increase social contact and support (Arean, 1993; Yost, Beutles, Corbishley & Allender, 1986) and regular contact with the patient's primary care physician has been suggested (Arean, 1993; Gallagher-Thompson & Thompson, 1995).

In addition to these general recommendations, the older adult literature includes a number of well-controlled clinical trials documenting the specific efficacy of psychosocial treatment for depression (Arean et al., 1993, Thompson, Gallagher, & Breckenridge, 1987; see Chapter 9, this volume). However, much less attention has been paid to the development of psychosocial treatments for anxiety among the elderly, and the need for further work in this domain has been noted repeatedly (Cartensen, 1988, Hersen & Van Hasselt, 1992; Niederehe, Cooley, & Teri, 1995). Given the voluminous body of work documenting the efficacy of cognitive behavioral treatments for anxiety in younger adults (Barlow, 1988, Beidel & Turner, 1991) it is not surprising that initial attempts to establish psychosocial interventions for older adults have focused on these approaches. However, the available literature is limited largely to clinical case studies and group comparisons with community volunteers reporting general anxiety symptoms.

A relatively large group of case studies has examined the use of cognitive behavioral interventions that have been demonstrated efficacious in younger adult samples. In particular, interventions including exposure, response prevention, relaxation training, and cognitive restructuring have been utilized to treat elderly patients with a range of anxiety disorders, such as GAD (King & Barrowclough, 1991), PD (Swales, Solfvin, & Sheikh, 1996), specific phobias (Thyer, 1981), and OCD (Calamari, Faber, Hitsman; & Poppe, 1994; Carmin, Ownby, & Pollard, 1995; Rowan, Holborn, Walker, & Siddiqui, 1984) The efficacy of cognitive behavioral interventions with a wide range of anxiety difficulties suggests strongly the utility of further work in this domain. However, conclusions from these reports alone can be drawn only cautiously given the absence of appropriate methodological controls.

Other more controlled research has examined the utility of cognitive behavior therapy (CBT) for the reduction of anxiety symptoms in nonclinical, community volunteers. In one of the earliest of these studies, DeBerry (1982) compared the effects of two versions of relaxation training with an attention control condition in a sample of older adult women volunteers with various anxiety complaints. Results demonstrated the efficacy of both relaxation training conditions, relative to the control group, on measures of state and trait anxiety. In a similar comparison, 24 older community volunteers reporting both anxiety and depressive symptoms were assigned randomly to receive relaxation training, CBT for depression, or a nonspecific control condition (Sallis, Lichstein, Clarkson, Stalgaitis, & Campbell, 1983). Results revealed significant reductions in both anxiety and depression across all treatment groups.

In a subsequent study, another community group of older adults with anxiety symptoms received relaxation training, cognitive restructuring, or an attention control condition

(DeBerry, Davis, & Reinhard, 1989). In this comparison, only relaxation training was effective in decreasing state anxiety, although trait anxiety and symptoms of depression were reduced at post-treatment across all conditions. In a more recent comparison with a larger group of community volunteers, the effects of progressive and imaginal relaxation training were examined relative to a wait-list control condition (Scogin, Rickard, Keith, Wilson & McElreath, 1992). Both types of relaxation training led to significant decreases in anxiety, relative to the control group, and treatment gains were maintained at one year follow-up (Rickard, Scogin, & Keith, 1994).

These studies together suggest that CBT, in particular relaxation training, may be beneficial for the treatment of anxiety in older adults. However, the sample sizes in many of these reports were small, and participants were not evaluated for the presence of diagnosable anxiety pathology. Only recently has a preliminary empirical trial examined the utility of cognitive behavioral interventions in older adults with well-diagnosed anxiety disorders.

In this comparison, the efficacy of CBT was evaluated relative to a nondirective supportive psychotherapy condition in a sample of 48 older adults with a principal diagnosis of GAD (Stanley et al., 1996). Treatment in both conditions was administered in a small group format over a period of 14 weeks. CBT followed the treatment approach described by Craske, Barlow, and O'Leary (1992) and included relaxation training, cognitive therapy, and systematic exposure to worry-related situations. Modifications to this treatment model included the use of a group format, as well as increased use of visual and written aids (e.g., outlines of session topics, written instructions for homework and monitoring assignments). Results revealed significant decreases at post-treatment for participants in both treatment conditions on self-report and clinician-rated measures of worry, anxiety, and depression. CBT also produced significant improvement in severity of specific fears, although psychometric limitations of the FQ restrict the conclusions which can be made in this regard. Results of a six month follow-up evaluation revealed maintenance of treatment gains in both conditions, with some continued improvement in severity of worry over time. Correlational analyses suggested that pretreatment severity of anxiety and ratings of treatment credibility were significant predictors of outcome. As such, these data further substantiate the potential utility of CBT (and other psychosocial interventions) for the treatment of anxiety among the elderly. However, study conclusions are limited given the omission of a no-treatment or wait-list control condition. Future research will need to replicate these findings in a better controlled design.

7.08.7 SUMMARY

Anxiety disorders are the most prevalent of all psychiatric conditions among elderly people and they pose a major public health problem for this population. Nevertheless, research addressing the prevalence, nature, and treatment of these conditions among elderly is in an infancy stage. No data are available regarding the prevalence of PTSD among the elderly, and the clinical picture of many anxiety syndromes in this segment of the population is as yet unclear. Much of the available literature is limited due to the significant dearth of well-established measures of anxiety among elderly people and the failure to utilize strict diagnostic criteria in the selection of clinical groups. The utility of measures already established for use with younger groups deserves further study in this regard. Additionally, new instruments that target specifically the unique features of anxiety among elderly people will need to be developed. In this domain, the focus will need to be not only on self-report instruments, but also on systematic methods of behavioral observation, clinician rating, and psychophysiological assessment. The development of more refined measures will assist in clarifying the difference between anxiety disorders and other syndromes that may produce similar clinical features, including depression, various medical conditions, sleep disorders, and cognitive dysfunction.

With the establishment of psychometrically sound assessment tools, more sophisticated treatment research should emerge. Pharmacological trials might focus on the relative efficacy of various antianxiety and antidepressant medication, and psychosocial treatment comparisons should evaluate further the utility of CBT and alternative interventions in well-diagnosed groups of older patients. Emphasis in all of these investigations should be given not only to the effects of treatment on symptom reduction, but also to the transfer effects of the interventions on associated clinical features, physical health, and social functioning. Durability of treatment response following both pharmacological and psychosocial treatments will need to be examined with well-controlled evaluations over long-term follow-up intervals, and findings will need to be generalized to patients recruited from a variety of settings (e.g., psychiatric clinics, primary care clinics) and from diverse sociocultural backgrounds.

7.09.1 INTRODUCTION

This chapter provides an overview of mood disorders in older adults. Issues addressed include: How well does the current diagnostic system map onto the types of affective disorders that are observed among older adults? How frequent are mood disorders among older adults? What is the connection of depression to suicide among older adults? What interventions are effective for preventing depression in old age, for alleviating episodes of depression, and for maintaining improvement and thwarting recurrence? Additionally, what is known about etiology is explored, emphasizing the complex influences that link affective symptoms, physical illness, and cognitive dysfunction. This material is then used to inform the discussion of assessment and treatment.

Although the relative proportions are unclear, a key differentiation is between depressive disorders that represent a continuation of conditions from earlier in the life cycle and disorders with first onset in old age. Throughout the chapter, therefore, this differentiation will be maintained, although regrettably the literature frequently does not provide sufficient information to divide the data in this manner.

The mood disorders include depressive disorders, both major depressive disorder and dysthymic disorder, and bipolar disorders. There is minimal literature on mania or bipolar illness in old age. Instead, gerontological researchers have paid most attention to either major depression or subsyndromal symptom constellations. While the task is to encompass all mood disorders, the emphases reflect the differential availability of literature.

Finally, attention is called to the importance of this material, given the common image of depression as characteristic of old age and the frequency with which depressive symptoms are used as outcome measures in research on aging.

7.09.2 DEFINITION AND CLASSIFICATION

Definitional problems underlie debates about prevalence and etiology. For this reason, different classification systems are reviewed and the effect of differences in criteria on decisions about diagnosis and rates of disorder is explored. The most commonly accepted classifications of mood disorders are those in the *Diagnostic and statistical manual of mental disorders* (*4th Edition; DSM-IV*; American Psychiatric Association, 1994) and the *International classification of disease* (*10th Edition*; *ICD-10*; World Health Organization, 1992). These include depressive disorders (major depressive disorder and dysthymic disorder) and bipolar disorders. It is not clear, however, how fully these conventional diagnostic categories represent the experience of affective disorders among older adults. For this reason, descriptions of several subtypes of depression are also presented that may better capture the syndromes prevalent in late life.

7.09.2.1 Standardized Classification Systems

7.09.2.1.1 DSM-IV

Major depressive disorder is defined in the *DSM-IV* by the presence most of the day, nearly every day, of dysphoria (depressed mood), anhedonia (diminished interest or pleasure in all or nearly all activities), appetite or weight disturbance, sleep disturbance, psychomotor agitation or retardation, loss of energy, worthlessness or guilt, inability to concentrate, and/or recurrent thoughts of death or suicide. At least five symptoms must be present, of which one must be either dysphoria or anhedonia. Symptoms attributed to uncomplicated bereavement, the direct physiological effects of a medical condition, or use of a substance (including medications), are excluded. A diagnosis of depressive disorder is made, however, if symptoms in a bereaved person persist longer than two months or include marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

Dysthymic disorder is characterized by chronicity and a lower level of severity than major depression. Depressive symptoms must be present for at least two years. If criteria for both major depressive and dysthymic disorder are met, both diagnoses are assigned, a condition commonly referred to as double depression.

Bipolar-I disorder is marked by alternating major depressive and manic episodes, resulting in impaired functioning. If the manic episodes are briefer and do not interfere with functioning (i.e., hypomanic episodes), the diagnosis of bipolar-II is assigned. Hypomanic episodes alternating with dysthymic symptoms are classified as cyclothymic disorder.

Depressive symptoms that do not meet the above diagnostic criteria, but can be attributed to a specific stressor, may be classified as adjustment disorder with depressed mood.

7.09.2.1.2 ICD-10

There is much similarity between *ICD-10* and *DSM-IV* for mood disorders. Depressive disorders are classified by severity, with moderate and severe equivalent to the *DSM-IV* category of major depressive disorder, and mild episode more closely resembling the provisional category of minor depression in the appendix of *DSM-IV*. *ICD-10* criteria for bipolar affective disorder, dysthymia, and cyclothymia are equivalent to the corresponding *DSM-IV* categories.

7.09.2.1.3 Earlier versions of DSM *and* ICD

Much of the currently available research on mood disorders is based on earlier versions of *DSM* and *ICD*, including *DSM-III* (American Psychiatric Association, 1980), *DSM-III-R* (American Psychiatric Association, 1987), *ICD-9-CM* (Commission on Professional Hospital Activities, 1978), and *ICD-9* (World Health Organization, 1977), or on the Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978). The RDC influenced changes appearing in *DSM-III*, which was published shortly thereafter. RDC mood disorder classifications include: major depressive disorder, minor depressive disorder, bipolar with mania (bipolar-I), bipolar with hypomania (bipolar-II), and intermittent depressive disorder. Changes in *DSM* categories since 1980 have been minimal, while some *ICD* classifications have been completely reworked during this time frame.

In the *DSM*, criteria for mood disorder have become somewhat more stringent with later revisions. A requirement that symptoms be clinically significant or cause impaired social, occupational, or other functioning was introduced in the *DSM-III-R* for dysthymia and in the *DSM-IV* for major depressive disorder. This criterion could affect diagnosis in older adults disproportionally, who may be less likely to engage in social or occupational roles in which impaired functioning could be observed. There have been significant changes in the specification of melancholic features, with *DSM-IV* criteria more closely resembling *DSM-III* than *DSM-III-R*. Bipolar-II disorder was added to *DSM-IV* as a new classification.

Perhaps the greatest changes have occurred between *ICD-9* and *ICD-10*. In the earlier version, mood disorders were classified as either a neurotic disorder or an affective psychosis. Since diagnostic criteria were not specified in detail in *ICD-9*, precise comparisons of classifications are not possible. Affective psychosis approximates the *ICD-10* category of depressive disorder with somatic symptoms, while a neurotic depression would be diagnosed in *ICD-10* as either depressive disorder without somatic symptoms or dysthymia. Due to the differences between classification systems (particularly between *ICD-9* and all other systems), caution should be exercised when comparing results of studies that were not based on a common rubric.

7.09.2.2 Symptom Presentation in Late Life

Although some scholars emphasize similarities between older and younger individuals in the experience of depressive symptoms, there is also an accumulating body of research identifying differences in symptom presentation in late life (for a review, see Caine, Lyness, King, & Connors, 1994). The most frequent differences include: lower prevalence of dysphoria, fewer ideational symptoms (e.g., guilt, suicidal ideation), and increases in selected somatic symptoms.

Several authors have reported a decreased likelihood of dysphoria as a symptom of depression in old age (e.g., Kongstvedt & Sime, 1992). In the Epidemiologic Catchment Area (ECA) sample, Gallo, Anthony, and Muthén (1994) found that older individuals were less likely to endorse an item comprising dysphoria or anhedonia than younger respondents with the same level of overall depression. Using a self-report symptom checklist, Gatz and Hurwicz (1990) found that depressed mood was neither higher nor lower in older adults; however, the older adults in their sample were less likely than other age groups to endorse items on a well-being subscale. Consequently, these authors speculate that older adults may be more likely to experience a lack of positive feelings than active negative feelings.

Age differences in ideational symptoms among depressed patients have been described by Musetti et al. (1989) and Small, Komanduri, Gitlin, and Jarvik (1986). They found lower levels of guilt and lower levels of a factor including self-blame and suicidal ideation. Even though older adults are more likely to complete acts of suicide than younger individuals (Gulbinat, 1996), they appear to be less likely to display suicidal ideation (Blazer, Bachar, & Hughes, 1987; Brown, Sweeney, Loutsch, Kocsis, & Frances, 1984). Brown et al. noted that lower levels of guilt were characteristic of late-onset cases.

The central question about somatic symptoms in depressed older adults is whether they are reliable indicators of depression or merely an artifact of the high comorbidity of physical illness in this age group. Blazer et al. (1987) found that older adults with melancholia were more likely than younger adults to have weight loss and constipation. In patients with major depression, older adults have been found more likely to have delusions, agitation, appetite disturbance, initial insomnia, and hypochondriasis than younger patients (Brodaty et al. 1991; Brown et al. 1984). No difference in somatic symptom presentation was found between early- and late-onset cases. Other investigators have found no age differences in somatic symptoms or preoccupation with physical health, either in depressed psychiatric patients (Kongstvedt & Sime, 1992) or among male patients with medical problems (Koenig, Cohen, Blazer, Krishnan, & Silbert, 1993). Using self-report depression symptom instruments, Kessler, Foster, Webster, and House (1992) found similar relationships with age for both mood and somatic symptom subscales. Finally, Davidson, Feldman, and Crawford (1994) found that physically disabled older adults who scored high on the somatic factor tended to score high on the other factors as well.

Regardless of how common or uncommon specific symptoms are in older adults, it is also important to know which of them are useful prognostically. The particular symptoms that best distinguish depressed from nondepressed older individuals seem to include loss of interest, lack of energy, sleep disturbance, suicidal thoughts, and feeling blue (Koenig et al., 1993; Norris, Snow-Turek, & Blankenship, 1995). Fatigue and changes in appetite and sexual activity did not, and may reflect physical comorbidity or normal aging.

7.09.2.3 Subtypes

Knowledge of the depressive symptoms most frequently experienced by older adults informs the discussion of several subtypes of depression or symptom constellations thought to be relevant in later life. The subtypes reviewed here include ones that can be accommodated within the diagnostic rubric (melancholia and delusional depression), experimental diagnostic categories (minor depression and mixed anxiety–depression), and other syndromes that may occur in older adults (masked depression, depletion syndrome, and hopelessness depression). There is also considerable convergence across many of these entities.

7.09.2.3.1 Melancholic

In the *DSM-IV*, individuals with a unique pattern of symptoms, including nearly complete loss of pleasure in most activities, lack of reactivity to pleasurable stimuli, a distinct quality of mood, depression worse in the morning, early waking, psychomotor retardation or agitation, weight loss, and excessive guilt, are diagnosed with major depressive disorder with melancholic features. At least one of the first two symptoms must be present. The criteria for melancholia in *ICD-10*, referred to as "somatic symptoms," includes the same symptom pattern as "melancholic features" in *DSM-IV* with the exception of distinct quality of depressed mood and excessive guilt. The term "endogenous" has also been used to refer to melancholic depression.

7.09.2.3.2 Delusional depression

Delusional depression is a depressive disorder with the presence of mood-incongruent delusions. It is diagnosed in *DSM-IV* and *ICD-10* by specifying psychotic features/symptoms. In

ICD-10, psychotic symptoms are further classified as mood-congruent or incongruent. There is mixed evidence concerning the relationship between delusional depression and age of onset. Meyers, Greenberg, and Mei-Tal (1985) found delusional depression to be more common in later-onset cases and in late-onset endogenous depression (Meyers, Kalayam & Mei-Tal, 1984). As mentioned earlier, Brodaty et al. (1991) found delusions to be more common in older adults than in younger adults. Nelson, Conwell, Kim, and Mazure (1989) and Baldwin (1995), on the other hand, found no such association.

7.09.2.3.3 Minor depression

As a result of concerns regarding the validity of diagnostic categories for older adults, the 1991 Consensus Conference on Depression in Late Life issued a call for research on "minor (subsyndromal) depression" (Blazer, 1994). Standardized study criteria for minor depression, included in the appendix of *DSM-IV*, are the same as those for major depressive disorder but require fewer symptoms. A similar definition has been referred to as "subdysthymic depression" (Mossey, Knott, Higgins, & Talerico, 1996) or simply "depressive symptoms" (Newmann, 1989; Wells et al., 1989). Several authors have used the term "minor depression," but defined it more inclusively, capturing dysthymia and adjustment disorder with depressed mood as well as dysphoria (Beekman et al., 1995; Koenig & Blazer, 1992; Parmelee, Katz, & Lawton, 1989).

Beekman et al. (1995) found that risk factors for major depression (family history of depression, previous episodes of depression) differed from those for minor depression (being unmarried, having smaller networks of social contacts, living in a large city, chronic disease, and functional limitations). These authors concluded that major depression may be more chronic, while minor depression may be more reactive to stressors. Although minor depression requires fewer symptoms than major depression, and the name implies a syndrome with lesser severity, the Medical Outcomes Study (Wells et al., 1989) revealed that even depressive symptoms in the absence of a depressive disorder were associated with more functional disability than most physical illnesses studied.

7.09.2.3.4 Mixed anxiety–depressive disorder

Another experimental category added to *DSM-IV* that may be relevant to older adults is mixed anxiety–depressive disorder. This proposed disorder is characterized by a combination of subsyndromal depression and anxiety symptoms. The research criteria require a persistent or recurrent dysphoric mood lasting at least one month, with at least four of these additional symptoms: difficulty concentrating, sleep disturbance, fatigue or low energy, irritability, worry, tearfulness, hypervigilance, anticipating the worst, hopelessness, or low self-esteem. Although mixed anxiety-depression was found in one study to be more prevalent in younger than in older age groups (Blazer et al., 1988), this subtype merits further research in an older population due to the obvious overlap between the specified symptoms and those found commonly in depressed older adults.

7.09.2.3.5 Masked depression

A further term used for older individuals is masked depression (Blumenthal, 1980). Also known as somatic depression, masked depression refers to a predominance of somatic symptoms without mood-related symptoms. As the term "masked" implies, diagnosis can be difficult due to the absence of the dysphoric mood that characterizes depression.

7.09.2.3.6 Depletion syndrome

Fogel and Fretwell (1985) proposed depletion syndrome as a new subtype of depression, characterized by predominant somatic and vegetative symptoms in depressed older adults with good premorbid psychosocial functioning and no evidence of psychosis. Newmann, Klein, Jensen, and Essex (1996) have pursued this concept, identifying a set of symptoms that occur together more frequently in older adults than in younger individuals. This constellation of symptoms differs from the depression syndrome in that self-deprecating feelings (self-blame and inappropriate guilt) are not present, dysphoric mood items are less prominent, and enervation, loss of interest in things, hopelessness, and loss of appetite are more prominent. Although sleep disturbance is associated with depletion syndrome, it does not include early morning awakening. Newmann et al. characterize this syndrome as "quieter" than major depression. In a longitudinal study, they found that individuals with depletion syndrome were more likely to die before the next time of measurement than those with depressive syndrome, suggesting that depletion syndrome may be related to a wearing down process. It is important to note that the only research on this subtype to date has been in a female population.

7.09.2.3.7 Hopelessness depression

This subtype was developed in younger populations (Abramson, Metalsky, & Alloy, 1989). Like depletion syndrome, it is characterized by decreased motivation, lack of energy, apathy, and psychomotor retardation, as well as by sad affect. Thus, applicability of this conceptualization to older adults seems warranted.

7.09.2.4 Categorical vs. Dimensional Systems

Although the focus has been on various categories used to describe mood disorders in older adults, depression has also been conceptualized as a continuum. Caine et al. (1994) recommend the use of a dimensional descriptive system encompassing the full range of mood syndromes and comorbid medical conditions. Unlike categorical diagnostic methods, depressive symptom checklists yield a rating on a continuous scale and are inclusive in approach. In general, scores relating to the presence or severity of individual symptoms are summed to provide a single rating of level of depressive symptomology. Since no symptoms are excluded due to etiology (e.g., bereavement, physical illness), a more complete picture of distress is provided.

7.09.3 PREVALENCE

7.09.3.1 Rates of Mood Disorders

Studies measuring depressive disorders have found a relatively low prevalence in late life. In a review of earlier studies, Kay and Bergmann (1980) concluded that the prevalence of depressive neuroses ranged from 4 to 9%, and that field surveys on affective psychoses were too limited to yield reliable information. Table 1 summarizes studies of the prevalence of mood disorders in late life that employed representative sampling methods and large sample sizes. The one-year prevalence of major depression among individuals aged 65 years and older ranges from a reported low of 0.9% in the ECA survey in the US (Weissman, Bruce, Leaf, Florio, & Holzer, 1991) to a high of 5.7% in a study of ethnic Chinese living in Singapore (Kua, 1992), with more studies finding rates at the low end of this range. Fewer studies have specifically measured rates of dysthymia in an older population. Due to the chronic nature of this disorder, only lifetime rates have been reported. Weissman and Myers (1978) found a 1.8% lifetime prevalence of dysthymic disorder among older adults using RDC. In the more recent ECA study, based on *DSM-III* criteria, Weissman et al. (1991) reported an overall rate of dysthymic disorder of 1.7% among those aged 65 years or older. Studies of bipolar disorder in older adults are even more rare. According to ECA data, one-year prevalence rates of bipolar disorder ranged from 0 to 0.4% across study sites, for an overall prevalence of 0.1%. Establishing the prevalence of other diagnostic subtypes, such as minor depression, is complicated by varying definitions of these entities.

7.09.3.2 Presence of Depressive Symptoms

Several studies have measured the prevalence of clinically significant depressive symptoms, without tying symptoms to diagnostic criteria for a depressive disorder. Rates of mood disorders suggested through the use of clinical cutoffs on depressive symptom checklists are shown in Table 2 for adults aged 65 years and older. These rates range from 9.0 to 16.9%. Rates found by these studies are generally high compared to studies using diagnostic criteria, as would be expected, since summary scores cannot distinguish between individuals with a disorder and those with subsyndromal levels of symptoms.

7.09.3.3 Age and Depression

In general, epidemiological studies have found lower rates of depressive disorders in older adults compared to other age groups, whereas studies measuring depressive symptoms have found elevated levels in late life, particularly after age 75 years (see Newmann, 1989, for a review). This outcome lends support to the notion that the symptoms experienced by older individuals may not map well onto existing diagnostic criteria.

The association between age and depression is further complicated by the consistent finding that older individuals report a lower lifetime prevalence of depression compared to younger individuals (Weissman et al., 1991). Since older adults have had more years in which to experience depressive episodes, this finding is remarkable. Several possible explanations have been posited. Some researchers have suggested that later-born generations in the twentieth century have experienced progressively higher rates of depression than those born earlier (e.g., Klerman et al., 1985). This cohort effect could explain relatively low rates of depression among those now old, and would predict that rates of depression in late life would rise as successive generations enter old age. A second hypothesis suggests that lifetime prevalence rates are

selectively biased in old age, with forgetting of symptoms exacerbated by cognitive impairment. In fact, research has found lifetime prevalence rates to be fairly unreliable at all ages (Kendler, Neale, Kessler, Heath, & Eaves, 1993). A third factor is selective mortality. Since depression has been associated with increased risk of mortality (Burvill, & Hall, 1994), depressed individuals would be less likely than nondepressed individuals to survive into old age. However, Klerman and Weissman (1889) argued that selective mortality is insufficient to explain observed differences, since a strong association between depressive disorders and subsequent death has not been consistently demonstrated.

It is not clear what proportion of depression in older adults within the community represents late-onset cases. Two studies of consecutive psychiatric admissions found approximately half to have first onset after the age of 60 years (Meyers et al., 1985; Steingart & Herrmann, 1991).

7.09.3.4 Gender

Studies of mixed age populations have consistently found the prevalence of major depressive disorders to be higher in women than in men. This sex difference is also evident for older adults. In both the ECA data (Weissman et al., 1991) and the Canberra study (Henderson et al., 1993), the rate of major depressive disorder in older women was 3.5 times the rate for older men. Evidence indicates, however, that this difference diminishes, or even reverses, in extreme old age. Equal prevalence rates for men and women with major depression were found by Girling et al. (1995) for individuals over 77 years and by Forsell, Jorm, von Strauss, and Winblad (1995) for nonagenarians. Wallace and O'Hara (1992) found that the sex difference on the Center for Epidemiologic Studies—Depression scale (CES-D) diminished in older age and was reversed in individuals aged 85 years and older.

In contrast to the sex ratio for major depressive disorder, bipolar disorder seems to occur with equal frequency in men and in women in mixed-age samples and in old age (Weissman et al., 1984).

7.09.3.5 Ethnicity/Race

Few studies report rates of mood disorders in older adults by race or ethnicity. Blazer, Burchett, Service, and George (1991) reported no differences between Black and non-Black older adults on a modified CES-D. In a national probability sample of older adults, Stallones, Marx, and Garrity (1990) found no differences in rates of major depression for Black and White men, but Black women were nearly twice as likely to have major depressive disorder as White women. Both Frerichs, Aneshensel, and Clark (1981) and Kemp, Staples, and Lopez-Aqueres (1987) found Latino older adults in Los Angeles to have especially elevated rates of depression. The authors suggest that income and education levels may account for ethnic differences. In the latter report, rates were highest among non-English speaking individuals, raising issues both of translation of terms and cultural understanding of the meaning of symptoms.

7.09.3.6 Special Populations

7.09.3.6.1 Medical inpatients and outpatients

The prevalence of mood disorders is higher in medical outpatients, medical inpatients, and residents of long-term care facilities than in the general population (see review by Koenig & Blazer, 1992). The few studies examining depressive disorders among older adult outpatients have reported widely varying rates. Barrett, Barrett, Oxman, and Gerber (1988) found major depression or minor episodic depression in 5.6% of patients over age 65 years in a general medical practice, with an additional 7.9% showing masked depression. In contrast, two studies of Veterans Administration (VA) outpatient clinic populations found rates of major depression of 23% (Norris, Gallagher, Wilson, & Winograd, 1987) and 31% (Okimoto et al., 1982).

Studies of older medical inpatients have yielded rates of major depression ranging generally from 6 to 13%, with an additional 15–30% displaying dysthymia, adjustment disorder, depressive disorders not otherwise specified, or dysphoria (Koenig & Blazer, 1992). As with outpatient samples, the highest rates of depression among older adult inpatients have been found in a VA setting. Kitchell, Barnes, Veith, Okimoto and Raskind (1982) found major depressive disorder in 45% of a sample of veterans.

7.09.3.6.2 Long-term care facilities

Studies of depression in institutional settings have found 6–16% meeting *DSM* criteria for major depression, and an additional 25–35% diagnosed with another type of depressive disorder or significant dysphoria (Henderson et al., 1993; Koenig & Blazer, 1992). Both Parmelee et al. (1989) and Mann, Graham, and Ashby 1984) found an approximately doubled risk among newly admitted residents compared to veteran residents or intrainstitution transfers.

Although few studies have examined rates of bipolar disorder in institutional settings, the ECA found a rate of 9.7% in nursing homes compared to a rate of major depression of 16.2% (Weissman et al., 1991).

7.09.3.6.3 Caregivers

Depressive disorders and depressive symptoms have been found in a high proportion of older adult caregiver samples, although methodological issues make comparisons with the general population difficult. In studies using diagnostic criteria ascertained by clinical interview, rates of depressive disorders among caregivers range from 23 to 46%, while virtually all studies measuring depressive symptoms have found elevated levels in this group (Schulz & Williamson, 1994). A problem with research on caregivers is lack of representative sampling, since most samples are drawn from individuals who have sought help (e.g., support group members) and therefore may be more distressed.

7.09.4 ETIOLOGICAL AND CORRELATED FACTORS

This section reviews factors that are related to clinically diagnosed depression and severity of depressive symptoms. Some of these variables are generally regarded as risk factors. However, the terminology of risk factors implies a temporal and causal relationship, whereas the terminology of correlated factors allows for reversed causal order, feedback mechanisms, or that both depression and the respective factor are the outcome of the same process. Variables encompassed in this section include physical health, cognitive dysfunction, interpersonal relations and stressful life events, and genetic risk.

When considering etiological and correlated factors, it is important to keep in mind that not all older adults who experience one or more of these factors necessarily become depressed. Why are some individuals vulnerable and others apparently resilient? Coping styles, perceived control and efficacy, and social support are among the variables that have been shown to mediate the relationship. These are relevant protective factors when designing preventive interventions and useful variables in accounting for individual differences in response to physical illness, interpersonal loss, and cognitive impairment.

7.09.4.1 Physical Health

Physical health status, which can be defined in terms of medical conditions and associated medication use, functional disability, pain, and subjective perceptions of poor health, has been found to be correlated with depression (Forsell et al., 1995; Heikkinen, Berg, & Avlund, 1995; Kennedy et al., 1989; Stallones et al., 1990). This is one of the most well-established correlations in studies of mood and aging. Several explanations for this association exist: physical illness and/or its treatment induce biological changes that trigger depressive symptoms; the same physiological factors underlie physical illness and depression; depression leads to physical illness by creating vulnerabilities, possibly neuroimmune, or by undermining self-care efforts such as medication compliance; physical illness is a stressful experience with which people have difficulty coping; or physical illness and depression co-occur as independent conditions. Thus, the powerful relationship between physical illness, associated conditions such as reduced activity, functional disability and perceptions of health, and depressive symptoms could reflect interdependence and continuing feedback loops of biological changes and psychological factors.

Biological changes induced by neurochemical, neuroanatomical, and functional alterations can create a liability for depression or for mania (see Ferrier & McKeith, 1991, and Leuchter, 1994, for reviews; Conn, 1989; Shulman, Tohen, Satlin, Mallya, & Kalunian, 1992). Preexisting disease processes, such as Parkinson's disease, medical conditions, such as hypothyroidism, or focal lesions may also induce affective changes (see Rubin, 1994 for review; Ferrier & McKeith, 1991). Cerebrovascular disease, including stroke and more minor insults such as deep white matter changes and lacunar infarcts, are particularly likely to precipitate depression (Lawlor & Anderson, 1995; Robinson & Starkstein, 1990), and vascular disease has a notable relationship with late-onset depression (Baldwin & Tomenson, 1995). Use of prescription medications for these conditions may precipitate or aggravate depression (Kinzie, Lewinsohn, Maricle, & Teri, 1986), as may psychotropic medications (Forsell et al., 1995).

Once present, depressive symptoms can worsen morbidity in medically ill individuals (Rapp, Smith, & Britt, 1990). This worsening may reflect a depression-induced vulnerability, a shared process, or a reaction to illness and disability. For example, stroke-induced paralysis could reduce mobility and increase dependence that has a negative impact on social and emotional functioning. Lyness, Caine, Conwell, King, and Cox (1993) found that in both younger and older depressed inpatients, physical disability was associated with depressive symptoms independent of, and likely additive to, medical illness. This finding is consistent with the conclusion that physical disability is associated with depressive symptomology across a range of physical conditions (Turner & Beiser, 1990), some of which do not have a purported biological basis for depression.

However, depression has also been found to increase risk of disability in individuals in the absence of significant health problems or disability (Bruce, Seeman, Merrill, & Blazer, 1994). Perceptions of health may be an important moderating variable given that perceived poor health or disability, irrespective of objective health status, can create depressogenic effects (Williamson & Schulz, 1992b). However, depressive symptoms also can influence self-perceived physical function (Cress et al., 1995).

The presence of pain contributes to the association between depression, disability, and medical illness. The association among illness, pain, disability, and depression has been examined in both community and institutionalized samples. In a community sample, Williamson and Schulz (1992a) found pain related to depression through its association with activity restriction. In institutionalized older adults, Parmelee, Katz, and Lawton (1991) found pain to serve as an independent predictor of depression.

7.09.4.2 Cognitive Dysfunction

Depression has been found to be associated with varying degrees of cognitive dysfunction. Three primary associations seem to exist: (i) memory loss can lead to depression; (ii) depression can be accompanied by cognitive impairment that is reversible, at least temporarily, in that it lifts when the depression is treated (referred to as "pseudodementia" or "depression related cognitive dysfunction"); and (iii) depression can co-occur with dementia, where depression represents a prodromal symptom, a comorbid condition possibly reflecting similar physiological factors, or a reaction to the dementia. The possibility of these variations, expanded below, underscores the difficulty in differentiating depression and dementia diagnostically.

Depression does not seem to be associated with a global decline in cognition. When an effect is observed, it tends to be limited to circumscribed deficits in specific domains, that is, executive functions and right-hemisphere tasks, although findings are equivocal across studies and among different measures of the same domain (see La Rue, 1992, for a review). For example, depressed middle-aged and older adults have been found to show deficits in nonverbal memory, select frontal lobe skills (Boone et al., 1994), and visual-spatial tasks (Lyness, Eaton, & Schneider, 1994), which Boone et al. interpret as premature "aging" of cognitive abilities. In contrast, O'Hara, Hinrichs, Kohout, Wallace, and Lemke (1986) found no significant verbal memory impairment in depressed elderly community-residing older adults. These findings are important because complaints about memory frequently accompany depression in older adults (O'Connor, Pollitt, Roth, Brook, & Reiss, 1990), and depression can affect concentration and hence performance on cognitive test batteries (Poon, 1992). Demonstrable cognitive deficits are observed more often among very severely depressed patients than in community samples. One study of older adult depressed inpatients found that impairment in learning and memory was related to longer duration of depression (La Rue, Goodman, & Spar, 1992). Further, elderly inpatients with psychotic features show poorer cognitive functioning than depressed patients without psychotic features (Kunik, Champagne, Harper, & Chacko, 1994).

The added difficulty with these studies is that it is possible that some of the more severe depressed patients are actually early dementia cases. Longitudinal follow-up suggests that a majority of cognitively impaired depressed patients who regain premorbid cognitive function after the depression is treated will develop dementia if followed long enough (Kral & Emery, 1989) and that degree of cognitive impairment in depression may predict who will develop dementia (Alexopolous, Meyers, Young, Mattis, & Kakuma, 1993). Various characteristics have been suggested to distinguish patients whose cognitive symptoms are due to depression alone from patients who are becoming demented, especially motivational disturbances and vegetative symptoms (Forsell, Jorm, & Winblad, 1994; Lazarus, Newton, Cohler, Lesser, & Schweon, 1987). History may be even more helpful than current features (see Kaszniak & Christenson (1994) for a comprehensive discussion of differential diagnosis).

Finally, there can be multiple, shared, or reciprocal causes. Although little is known about the cognitive dysfunction of depressed, demented individuals, there is some suggestion that depression worsens the cognitive impairment (Fitz & Teri, 1994). Moreover, demented patients with co-occurring depression show some cognitive improvement when depression is treated (Greenwald et al., 1989). Gross cognitive impairment concomitant with later age of onset of depression may suggest a shared biological vulnerability (Steingart & Herrmann, 1991). Awareness of deficits caused by dementia may engender dysthymia (Migliorelli et al., 1995; Seltzer, Vasterling, & Buswell, 1995). Some observers feel that depressed mood correlates negatively with degree of impairment, which intimates the role of awareness, although others have found no association between awareness and illness (Ballard, Cassidy, Bannister, & Mohan, 1993).

7.09.4.3 Interpersonal Relationships and Stressful Life Experiences

Both diagnosed depression and depressive symptoms have been found to be related to interpersonal difficulties (Hinrichsen & Zweig, 1994). This association may reflect three primary processes: (i) depression strains and disrupts interpersonal relationships, (ii) depression influences an individual's perception of social relationships; and (iii) unsupportive, demanding, sparse or nonreciprocal, nonequitable interpersonal interactions precipitate depression. Whether or not depression is an outcome of these processes seems to be determined, in part, by an individual's level of assertiveness (Kogan, Van Hasselt, Hersen, & Kabacoff, 1995), self-efficacy, or personal control (Krause, Hertzog, & Baker, 1992), degree of social embeddedness (Adelmann, 1994) and concurrent stressors.

What is known about interpersonal difficulties of depressed older adults tends to be derived from studies of social support that often are examined in the context of stressful life events. These events provide the occasion for emotional support and tangible assistance (Dean, Kolody, & Wood, 1990; Russell & Cutrona, 1991). Stressful life experiences include discrete, disruptive negative life events, chronic strains, and daily hassles. They may or may not be predictable or under a person's control. Often a discrete event precipitates chronic strains or hassles. Some common events with which older adults often must cope are widowhood, deaths of family and friends, caregiving, and the need for institutionalization. These events have been found to be associated with depression (see Murrell & Meeks, 1992 for a review). Declining health, increasing disability, and cognitive dysfunction are also stressful experiences that have been discussed earlier.

As with declining health and cognitive dysfunction, the causal direction of the association between stressful experiences, disrupted interpersonal relationships, and depression is controversial. However, a likely shared mechanism for depression is the depletion of resources (Hobfoll & Wells, in press). Identity, independence, and perceived control or efficacy can be threatened. Stressful experiences may result in disrupted relationships. Depressed individuals may act in ways that alienate their support network, or losses in a support network can precipitate depression. These processes all have implications for psychotherapeutic intervention.

One of the most important loss events is bereavement. Depressive symptoms following loss of spouse vary in relation to characteristics of the death (Gilewski, Farberow, Gallagher, & Thompson, 1991), quality of the relationship and degree of attachment with the deceased (Levy, Martinowski, & Derby, 1994; Murrell & Himmelfarb, 1989), concurrent stressors (Levy et al., 1994), timing and type of social support received (Schuster & Butler, 1989), and perceived competencies (Lund, Caserta, Dimond, & Shaffer, 1989).

Depressive symptoms or bereavement-related depression have been distinguished from grief, or the psychological and physiological reactions to the loss (Marwit, 1991), although both responses are time-limited. However, sometimes grief becomes complicated and the individual fails to return to preloss levels of well-being (Prigerson et al., 1995). Symptoms include crying, being stunned by loss, searching and yearning for the deceased, disbelief about the death, and preoccupation with thoughts of the deceased.

The distinction between grief and depression may explain some inconsistencies in previous studies on depression and loss events. Few investigations have examined the relationship between complicated grief and depression. Gilewski et al. (1991) found that levels of depression at the time of bereavement predicted subsequent adjustment. Hays, Kasl, and Jacobs (1994) and Lichtenstein, Gatz, Pedersen, Berg, and McClearn (1996) observed elevated depressive symptoms prior to the actual loss, with no significant difference between the period directly before the death and the period right after the loss. This pattern seems to be consistent with anticipatory grieving, a process that others have suggested may facilitate adaptation to bereavement (Levy et al., 1994).

7.09.4.4 Genetic Risk

Heritability of major depressive disorder has been studied using family, twin, and adoption designs in younger adults but not in older adults. It is generally accepted that there is some genetic involvement in etiology, that recurring episodes of depression suggest a more heritable form of the disorder, and that early-onset depression has greater genetic determination than late-onset depression (Moldin, Reich, & Rice, 1991). Baldwin and Tomenson (1995) found family history of depression in about a third of early-onset cases compared with 5% of late-onset cases (mean age of onset = 74 years).

In adult samples, Torgersen (1986) reported concordance rates of 27% for monozygotic (MZ) and 12% for dizygotic (DZ) twin pairs from a Norwegian sample and he estimated the heritability of major depression to be 54%. In a Danish twin sample, Bertelsen, Harvald, and Hauge (1977) found concordance rates for unipolar depression of 39% for MZ and 12.5% for DZ pairs. In the Swedish Adoption/Twin Study of Aging, with twin pairs all aged 50 and older, concordance rates for scoring 16 or higher on the CES-D were 33% in MZ and 12% in DZ pairs (Gatz, 1992). Using a British twin register, McGuffin, Katz, Watkins, and Rutherford (1996) reported concordance rates of 46% in MZ and 20% in DZ pairs for *DSM-IV* diagnosed major depression, resulting in heritability estimates of 48–75% dependent upon true population prevalence.

Heterogeneity in etiology is likely. Torgersen (1986) found that, while partners of probands with major depression were apt to have major depression, dysthymic disorder, or depressive adjustment disorder, concordance rates for dysthymic disorder were low in both MZ and DZ twin pairs. Kendler, Neale, Kessler, Heath, and Eaves (1992), using adult twins, suggest that genetic liability to major depression and to generalized anxiety disorder is influenced by the same genetic factors but different environmental experiences.

Consistent with the notion that genetic factors for early-onset depression are distinct from those for late-onset depression, van Ojen et al. (1995a, 1995b) found that older adults with depression accompanied by cognitive impairment were likely to have no history of psychiatric illness themselves and a family history of dementia or of Down's syndrome rather than a family history of depressive disorder. Those depressed older adults who reported both personal and family history of mental illness did not have impaired cognitive performance.

More than major depression, manic-depressive disorder has generally been regarded as running in families, and twin studies have suggested greater genetic influence for bipolar than for unipolar disorder (Bertelsen et al., 1977; Torgersen, 1986). Shulman et al. (1992) found that elderly patients admitted to a hospital for mania were more likely to have a family history suggestive of genetic predisposition compared with elderly admissions for major depression.

7.09.5 ASSESSMENT

In this section the focus is on psychometric properties, measurement efficiency, and measurement invariance of instruments used to assess depression. There follows a discussion on how validity is influenced by uncertainties about the diagnostic criteria in older adults and whether depression is the same across age and within different subgroups, defined by gender, ethnicity, or comorbid conditions (for other reviews and recommendations about measuring depression in older adults, see Pachana, Gallagher-Thompson, & Thompson, 1994, and Scogin 1994).

The efficiency of an assessment instrument can be gauged in terms of several metrics. Sensitivity is proportion of correctly identified depressed cases; specificity is proportion of nondepressed cases correctly identified; positive predictive power (PPP) is probability that a score at or above the clinical cutoff will correspond to a diagnosis of depression; negative predictive power (NPP) is probability that a score below the cutoff will correspond to the absence of a diagnosis of depression. PPP and NPP are influenced by population prevalence. The efficiency of any given cutoff will change with the base rate for depression. Because base rates are known to vary with cognitive impairment, physical illness and gender, efficiency can be affected. Variability in efficiency will also result when there are differences between groups in the underlying construct.

Assessment instruments are grouped on the basis of whether they are self-report or interview-based and by the population with whom they were developed. Interview-based measures include observer-rated measures and structured interviews. Structured interviews have two general formats: one applies diagnostic algorithms upon completion; the second incorporates the algorithms into the structure of the interview (i.e., if a required criterion is not met, the remaining questions are skipped).

7.09.5.1 Self-report Instruments

7.09.5.1.1 Depression scales developed with mixed-age samples

The Beck Depression Inventory (BDI; Beck, Ward, Mendelson, Mock, & Erbaugh, 1961) includes 21 items, each including four alternative statements ranging in order of severity from zero to three. Conventional cutoffs are 0–9 for normal range, 10–18 for mild to moderate depression, 19–29 for moderate to severe depression, and 30–63 for severe depression (Beck, Steer, & Garbin, 1988). For the 13-item short form (Beck & Beck, 1972), 0–4 corresponds to none or minimal depression, 5–7 to mild depression, 8–15 to moderate depression, and 16 or higher to severe depression.

The BDI has demonstrated test–retest and split-half reliability as well as concurrent validity with older adults (see Gallagher, 1986). With a cutoff of 10, the BDI has shown good efficiency with older depressed psychiatric outpatients (100% sensitivity, 96% specificity, 100% PPP, 100% NPP; Olin, Schneider, Eaton, Zemansky, & Pollock, 1992). In a sample seeking outpatient mental health services, Kogan, Kabacoff, Hersen, and Van Hasselt (1994) found that a cutoff of 22 maximized efficiency, yielding 64% sensitivity and 73% specificity.

The BDI has good efficiency in older medical outpatients (Rapp, Parisi, Walsh, & Wallace, 1988) and medical inpatients (Norris et al., 1987). Cognitively impaired individuals have been found to have difficulty comprehending the format (Lyons, Strain, Hammer, Ackerman & Fulop, 1989) and the BDI may be less sensitive to detecting major depression in older men when compared with older women (Allen-Burge, Storandt, Kinscherf, & Rubin, 1994).

The other conspicuous feature of the BDI lies in its inclusion of somatic symptoms. Zemore and Eames (1979) demonstrated that age differences on the BDI could be explained entirely by the somatic symptoms, with no age differences on the more cognitive symptoms.

The Zung Self-rating Depression Scale (SDS; Zung, 1965) contains 20 items, 10 worded positively, and 10 negatively. Items are on a one to four scale; raw scores are converted into a percentage by dividing the sum of all questions by 0.80. Conventional cutoffs are 25–43 for no depression, 50–59 for mild to moderate depression, 60–69 for moderate to severe depression, and 70 or over for severe depression (Zung, 1967). Older adults have shown higher normal baseline scores than the validation sample (Zung, 1967) which may be attributed to the large number of items about somatic symptoms (Berry, Storandt, & Coyne, 1984). Reliability has been found to be moderate or low, particularly among the oldest old, and sex and age differences in factor structure have been suggested (Kivela & Pahkala, 1986; Kivela & Pahkala, 1987; McGarvey, Gallagher, Thompson, & Zelinski, 1982). In medically ill inpatients, the SDS has been found to have a 58% sensitivity and 87% specificity using a cutoff score of 60 (Kitchell et al., 1982) in comparison with an 82% sensitivity–87% specificity in medical outpatients (Okimoto et al., 1982). A 10-item interviewer-assisted form has been developed and validated for older adults (Tucker, Ogle, Davison, & Eilenberg, 1986). A cutoff score above 70 is recommended for the 10-item form.

The Center for Epidemiological Studies—Depression Scale (CES-D; Radloff, 1977) is a 20-item measure designed for large-scale epidemiological surveys. It can be self-administered, by paper-and-pencil or using computer speech recognition (Muñoz, Gonzales, & Starkweather, 1995), or used in an interview, face-to-face or by telephone (George, Blazer, Hughes & Fowler, 1989). Four items are worded positively and are reverse scored; these items have a particularly high rate of omission or response bias (Callahan & Wolinsky, 1994; Gatz & Hurwicz, 1990). Scores range from zero to 60. A score of 16 or more is used as the conventional cutoff for clinical depression, although a cutoff score of 20 may have increased efficiency with older adults (see Radloff & Teri, 1986; Murrell, Himmelfarb, & Wright, 1983). Several shorter forms have been developed specifically for use with older adults by collapsing response categories and giving only 10 or 11 of the items (Andresen, Malmgren, Carter, & Patrick, 1994; Kohout, Berkman, Evans, & Cornoni-Huntley, 1993). The CES-D has probable measurement invariance across age (Hertzog, Van Alstine, Usala, Hultsch, & Dixon, 1990), culture (Heikkinen et al., 1995), and physical health or disability (Davidson et al., 1994). Although the same broad factors emerge, there are differences across gender and ethnic or racial subgroups with respect to factor loadings and placement of specific items on factors. Garcia and Marks (1989) and Callahan and Wolinsky (1994) emphasize that these differences imply sociocultural differences in the expression of depression.

Two self-report forms of the observer-rated Hamilton Rating Scale for Depression (HRSD) have been developed: the Carroll Rating Scale for Depression (CRS; Carroll, Feinberg, Smouse, Rawson, & Greden 1981; Feinberg, Carroll, Smouse, & Rawson, 1981; Smouse, Feinberg, Carroll, Park, & Rawson, 1981) and the Hamilton Depression Inventory (HDI; Reynolds & Kobak, 1991). In the CRS, 52 "yes/no" items replace the HRSD severity ratings. A score of 10 is the recommended clinical cutoff. Koenig, Meador, Cohen, and Blazer (1988, 1992) examined a 12-item short version of the CRS in medical inpatients

(BCDRS; Duke Depression Evaluation Schedule for the Elderly, 1988). A cutoff of six yielded the best efficiency.

The Inventory to Diagnose Depression (IDD; Zimmerman & Coryell, 1987; Zimmerman, Coryell, Corenthal, & Wilson, 1986) is a 22-item instrument designed to diagnose major depressive disorder according to *DSM-III* criteria and to provide information about symptom severity and duration. Although the IDD has been used with older adults, psychometric properties are unknown.

7.09.5.1.2 Instruments devised specifically for use with older adults

The Geriatric Depression Scale (GDS; Yesavage et al., 1983) includes 30 "yes/no" items, 10 reverse scored. A cutoff of 11 demonstrates good sensitivity (84%) and specificity (95%; Yesavage et al.) and adequate hit rates (17% false-negative rate, 18% false-positive rate; Dunn & Sacco, 1989) in community-dwelling older adults; good overall efficiency in psychiatric outpatients preselected for major depression (96% sensitivity, 96% specificity, 96% PPP, 96% NPP; Olin et al., 1992); and good sensitivity (89%) but poorer specificity (75%) and positive predictive value (27%) in older medical inpatients when compared with psychiatric interview (Koenig et al., 1988; Koenig, et al., 1992). Others suggest a cutoff of 14–16 for best efficiency (Burke, Houston, Boust, & Roccaforte, 1989; Kogan et al., 1994). Other evidence suggests that the GDS maintains its reliability and validity when administered over the telephone (Burke, Roccaforte, Wengel, Conley, & Potter, 1995).

The GDS has been found less effective in the detection of major depression in older men when compared with older women (Allen-Burge et al., 1994). It appears to be reliable and valid for older, medically ill outpatients (Norris et al., 1987), hospitalized individuals (Lyons et al., 1989; Rapp et al., 1988), and noncognitively impaired nursing home residents (Lesher, 1986), although some items are sensitive to health status (Fischer, Rolnick, Jackson, Garrard, & Luepke, 1996). There is some suggestion that it is insensitive to detecting minor depression (Harper, Kotik-Harper, & Kirby, 1990; Parmelee et al., 1989). Some older respondents have expressed dissatisfaction with the "yes/no" format (Fischer et al., 1996).

Use of the GDS in cognitively-impaired older adults is equivocal. When identifying depression in mildly to moderately demented individuals, Lichtenberg, Marcopulos, Steiner, and Tabscott (1992) found that a cutoff of 11 yielded good sensitivity (82%) and specificity (88%). With geriatric assessment center clients, Burke, Nitcher, Roccaforte, and Wengel (1992) found that a cutoff of 14 yielded the highest combined sensitivity (70%) and specificity (78%). Other studies show that the GDS does little better than chance as a screening measure for depression in cognitively-impaired individuals (Burke et al., 1989; Kafonek et al., 1989).

A 15-item short form of the GDS (Lesher & Berryhill, 1994; Sheikh & Yesavage, 1986) retains the same "yes/no" format and the same ratio of positively- and negatively-worded items. A cutoff of five is recommended. The GDS short form has good efficiency with medically ill skilled nursing facility residents (Baker & Miller, 1991) and older primary care surgery attenders (sensitivity 91%, specificity 72%, NPP 94%; D'ath, Katona, Mullan, Evans, & Katona, 1994), but poorer efficiency in ethnically heterogeneous populations (Cwikel & Ritchie, 1988) and in cognitively-impaired individuals (Burke, Roccaforte, & Wengel, 1991; Lesher & Berryhill, 1994).

7.09.5.1.3 Multidimensional measures with depression subscales

The 567-item Minnesota Multiphasic Personality Inventory-2 (MMPI-2; Butcher, Dahlstrom, Graham, Tellegen, & Kaemmer, 1989) includes a 57-item depression scale. Little is known about the measurement properties of the MMPI-2-D with older adults. One 15-item short form of the MMPI-D was developed and construct-validated using a sample of older adult male inpatients (Dush & Hutzell, 1986). Another short form has been used for detecting depression in cognitively-impaired older adults (Ward, Wadsworth, & Peterson, 1994).

The Symptom Checklist 90—Revised (SCL-90-R; Derogatis, 1977), as well as its precursors, the SCL-90 and the Hopkins Symptom Checklists (HSCL), assess distress on a wide range of psychiatric symptoms. The depression subscale on the SCL-90-R comprises 13 items. A 53-item short version of the SCL-90, entitled the Brief Symptom Inventory (BSI; Derogatis & Melisaratos, 1983), includes the depression dimension, reduced to six items. Norms have been published for use with community-dwelling older adults (Hale, Cochran, & Hedgepeth, 1984) and with caregivers (Anthony-Bergstone, Zarit, & Gatz, 1988). The BSI depression subscale excludes all somatic items. For medically ill patients, high false-negative rates have been reported, particularly those with minor depression (Harper et al., 1990).

Other self-report mood instruments that sometimes appear in the literature are the Multiple Affect Adjective Check List (MAACL:

Zuckerman & Lubin, 1965; MAACL-R: Zuckerman & Lubin, 1985) and the Profile of Mood States (POMS; McNair, Lorr, & Droppleman, 1971/1981/1992) or a shortened form (Guadagnoli & Mor, 1989). Properties with older adults are not well known.

7.09.5.2 Observer-rated Inventories

The Hamilton Rating Scale for Depression (Hamilton, 1960; Hamilton, 1967) is a 17-item instrument that was designed to measure frequency and intensity of depressive symptoms in individuals with major depressive disorder. Ratings are made using either a five- or a three-point scale, yielding total scores from zero to 61. Conventional clinical cutoff scores range from 14 to 20, with 17 being the most common in pharmacological research (see Reynolds & Kobak, 1991). The HRSD has demonstrated reliability, validity, and efficiency in older adults (Stukenberg, Dura, & Kiecolt-Glaser, 1990).

Cognitively-impaired, medically ill older adults have shown difficulty understanding, responding to, and completing the questions (Baker & Miller, 1991) and use of the HRSD for identifying depression in demented individuals has mixed results (Lichtenberg et al., 1992; Vida, Des Rosiers, Carrier, & Gauthier, 1994a). With a cutoff of 17, the HRSD showed 9% sensitivity and 92% specificity in mild to severely demented hospitalized patients. However, a cutoff of seven maximized efficiency, yielding 90% sensitivity and 63% specificity. A structured interview guide has been developed for the HRSD (SIGH-D; Williams, 1988) to standardize the way in which rating information is obtained; its use in older adults is unknown.

Another observer-rating inventory that more often appears in European literature is the Montgomery–Åsberg Depression Rating Scale (MADRS; Montgomery & Åsberg, 1979).

The Geriatric Depression Rating Scale (GDRS; Jamison & Scogin, 1992) was developed specifically for older adults. It includes 29 of the 30 items on the GDS and six somatic items to conform to RDC criteria. A cutoff of 20 can be used to discriminate depressed and nondepressed individuals (88% sensitivity, 82% specificity).

7.09.5.3 Structured Interviews

7.09.5.3.1 Instruments designed for mixed ages

The Present State Examination (PSE; Wing, Birley, Cooper, Graham, & Issacs, 1967) uses a standardized question format from which a computer program (CATEGO) yields behavioral syndromes that approximate the *ICD* diagnostic categories.

The Schedule for Affective Disorders and Schizophrenia (SADS; Endicott & Spitzer, 1978) is a semistructured interview developed in conjunction with the RDC. There are three versions: regular SADS, which queries severity of symptoms during the preceding week and at the time when they were the most severe during the current episode; lifetime version (SADS-L); and the version for measuring change (SADS-C). The SADS has been used with older adults. Efficiency is good (82% sensitivity and 93% specificity; Gallagher, Breckenridge, Steinmetz & Thompson, 1983) when compared with the BDI as a criterion measure.

The National Institute of Mental Health Diagnostic Interview Schedule (DIS; Robins, Helzer, Croughan, & Ratcliff, 1981) is a structured interview used in the ECA. Both current and lifetime diagnoses using *DSM-III* and RDC criteria can be made by computer.

The Composite International Diagnostic Interview (CIDI; Robins et al., 1988) was designed for cross-cultural epidemiologic and comparative studies of psychopathology in general populations, whereas its companion, the Schedules for Clinical Assessment in Neuropsychiatry (SCAN), was intended for use in clinical samples. The CIDI is constructed in diagnostic modules that can be extracted and administered on their own. These modules yield both *DSM-III-R* and PSE principal diagnoses, each with its own set of diagnostic computer programs. CIDI short screening scales are available for quicker administration (Kessler & Mroczek, 1993).

The Structured Clinical Interview for *DSM-III-R* (SCID; Spitzer, Williams, Gibbon, & First, 1992) provides current and lifetime diagnoses. It has been revised for *DSM-IV*. It is intended to be administered by clinicians and makes allowance for clinical judgement in modifying and supplementing the interview (Spitzer et al.). Use of information from multiple sources to inform rating decisions is encouraged. There are two versions of the SCID: the SCID-P (Patient) and the SCID-NP (Nonpatient). The major depression module of the SCID-P has been studied with older adults (Segal, Herzen, Van Hasselt, Kabacoff, & Roth, 1993).

7.09.5.3.2 Instruments designed for older adults

The Geriatric Mental State examination (GMS; Copeland et al., 1976) is a semistructured interview from which the AGECAT computer program is used to assign diagnoses and confidence ratings for each diagnosis.

Many of the 541 items were derived from the PSE. AGECAT depression diagnoses have been shown to have a sensitivity of 80%, a specificity of 89%, and a PPP of 71% in physically ill hospitalized older adults (Ames, Flynn, Tuckwell, & Harrigan, 1994).

The Geriatric Mental State Schedule-Depression Scale (GMSS-DS; Ravindran, Welburn, & Copeland, 1994) is a 33-item rating scale derived from the GMS, designed to be sensitive to symptomatic changes in depression with treatment in older adults.

The Comprehensive Assessment and Referral Evaluation (CARE; Gurland et al., 1977–78) uses a shortened form of the GMS as part of a comprehensive assessment package of health and social problems of elderly community residents. There is a 19-item depression/demoralization scale on the CORE–CARE (Golden, Teresi, & Gurland, 1984). The GMS–AGECAT and CARE are used in differential diagnosis of depression and dementia.

7.09.5.4 Assessing Depression in Cognitively-impaired Older Adults

Measures developed specifically to assess depression in cognitively-impaired individuals tend to use simple formats and to incorporate informant information and direct behavior observations. Information from collaterals has been demonstrated to provide an accurate, independent indicator of depression (Gilley et al., 1995; Logsdon & Teri, 1995), although discrepancies from patient report or unavailability of a collateral can pose problems in interpretation (Gilley et al.; Moye, Robiner, & Mackenzie, 1993; Ott & Fogel, 1992; Teri & Wagner, 1991).

Measures include the Cornell Scale for Depression in Dementia (CSDD; Alexopoulos, Abrams, Young, & Shamoian, 1988), the National Institute of Mental Health Dementia Mood Assessment Scale (DMAS; Sunderland et al., 1988), Columbia University Scale for Psychopathology in Alzheimer's disease (CUSPAD; Devanand et al., 1992), Canberra Interview for the Elderly (CIE; MacKinnon et al., 1993), Cambridge Mental Disorders of the Elderly Examination (CAMDEX; Roth et al., 1986), the Neurobehavioral Rating Scale (NRS; Sultzer, Levin, Mahler, High, & Cummings, 1992), and the Psychogeriatric Assessment Scales (PAS; Jorm et al., 1995).

The overlap of symptoms of depression and dementia raises difficult questions for the diagnostician. Vida, Des Rosiers, Carrier, and Gauthier (1994b) examined the validity of RDC criteria for major and minor depression in individuals with Alzheimer's disease (AD). They found that three criteria were not associated with major depression (difficulty with concentration or thinking, excessive self-reproach or guilt, anhedonia or apathy), whereas nonverbal manifestations of depression, resentfulness, irritability, anger or complaining, and demandingness or clinging dependency, showed the strongest association with major depressive disorder. Diagnostic criteria for minor depression remained valid.

7.09.5.5 Assessing Depression in Older Adults with Poor Physical Health

Assessment of depression in individuals with comorbid medical illness or disability has been an area of focused attention because of ambiguity in the interpretation of somatic symptoms. Several strategies have been undertaken: (i) development of new instruments, (ii) development of instruments that eliminate somatic symptoms or substitute cognitive/affective symptoms for somatic ones, and (iii) use of alternative diagnostic schemes that count all criterion-related symptoms and do not require judgments about etiology.

Koenig, Cohen, Blazer, Meador, and Westlund (1992) developed a scale with 11 items derived from the GDS and the CRS, selected for their predictive validity in medically ill individuals. When examined in a sample of men over age 65 years admitted to a medical and neurological VA service, a cutoff score of three yielded a sensitivity of 83% and specificity of 77%. The scale showed moderate correlations with other self-report measures. Evans (1993) developed the 15-item Evans Liverpool Depression Rating Scale (ELDRS) for detection of depression in physically ill older adults. It obtains both patient and collateral information in "yes/no" format. The ELDRS has been found to have adequate interrater reliability and good efficiency using a cutoff of 5/6 (sensitivity of 88–91% and specificity of 85–96%).

Rapp and Vrana (1989) examined the sensitivity and specificity of conventional SADS/RDC depression diagnoses, which exclude somatic symptoms judged to be secondary to organic condition, compared with a modification of the RDC that reassigned diagnoses after substituting nonsomatic symptoms for somatic symptoms. Fully 96% of individuals were classified the same way with both sets of criteria; the alternative criteria showed 87% sensitivity and 100% specificity. Eliminating the somatic symptoms without replacement, however, resulted in poorer classification. Koenig, Pappas, Holsinger, and Bachar (1995) evaluated the reliability of six diagnostic strategies varying in inclusivity. Some strategies eliminated fatigue and anorexia. Some replaced four somatic symptoms (fatigue, anorexia/weight loss, psychomotor retardation, impaired concentration) with four cognitive/affective symptoms (irritability, tearfulness, social withdrawal, feeling punished). When structured interviews were used, clinicians were able to determine reliably whether major depression was present regardless of diagnostic strategy. These studies suggest that there is no advantage to abandoning the *DSM-IV* in medically ill older adults, but that modified criteria may be easier and more accurate than the conventional system requiring judgments about the cause of somatic symptoms.

7.09.6 SUICIDE

A discussion of affective disorders in late life would be incomplete without consideration of suicide among this population. Death by suicide is more common among older adults than at any other age. Although most depressed older adults do not commit suicide, many older adults who do commit suicide are depressed.

7.09.6.1 Rates

The suicide rate for older adults in most countries is higher than that of any other age group (Gulbinat, 1996). Among nations reporting to the World Health Organization, rates of suicide for older men are up to seven times higher than adolescent male suicide rates (Gulbinat, 1996). Male suicides among all ages are two to three times more frequent than female suicides (Gulbinat, 1996). Rates also vary by race and ethnic background. In the US, suicide rates are highest among Native Americans and Whites, followed by people of Asian origin and Blacks, with people of Latino origin having lower rates of suicide than non-Latino origin. Gender, racial, and ethnic differences in suicide rates are most pronounced among older adults (McIntosh, 1992).

7.09.6.2 Methods

Methods used by older adults to commit suicide are generally less amenable to intervention than those used by younger age groups (De Leo & Diekstra, 1990). In the US, guns are used to commit suicide more frequently than any other method, both by men and women (Kaplan, Adamek, & Johnson, 1994; McIntosh, 1992). This is true of all ages, but to the greatest extent in late life. In Finland, hanging is the leading method of suicide for all ages, with the proportion of suicides using this method greatest in old age. In most Western countries, over 85% of older adult suicides involve hanging, poisoning, or drowning, with hanging more common in men and poisoning more characteristic of women (De Leo & Diekstra, 1990). In Japan, the most frequently used methods in late life are hanging, drowning, and jumping.

A unique feature of older adult suicide is the small window of opportunity for intervention. The ratio of attempted to completed suicides among older adults has been estimated at 4:1, whereas this ratio among all ages is estimated at 20:1, and among youth it is thought to be as high as 200:1 (McIntosh, 1992; Parkin & Stengel, 1965). This difference could reflect several factors: the selection of less reversible means, which in itself can be a sign of increased lethality of intent, decreased powers of recuperation (Lindesay, 1991), or isolation from rescue. Older adults have also been found to be less likely to express suicidal ideation than younger adults (Blazer et al., 1987), a factor further complicating assessment efforts.

7.09.6.3 Depression and Suicide

Depression and suicide are linked closely throughout the lifespan. Individuals who are depressed are more likely to commit suicide, and individuals who committed suicide were more likely to have been depressed. On a neurobiological level, the same serotonin pathways have been implicated in depression and suicide, particularly in violent suicides (Åsberg, Nordström, & Träskman-Bendz, 1986). Moreover, the association between depression and suicide is strongest in late life.

In a review of follow-up studies, Miles (1977) concluded that 15% of depressed individuals of all ages would eventually die by suicide. Gardner, Bahn, and Mack (1964) calculated suicide rates for individuals with affective psychosis to be 207/100 000 for those under age 55 years and 475/100 000 for those aged 55 years or older. Psychological autopsy studies in England and the US have found evidence for affective disorders in 83–87% of older adults who committed suicide (Barraclough, Bunch, Nelson, & Sainsbury, 1974; Conwell, Olsen, Caine, & Flannery, 1991), while a psychological autopsy study in Finland found depressive disorders in 67% of suicides who were over age 60 years (Henriksson, Marttunen et al., 1995). Substance use disorders are also prevalent in older suicides (either alone or comorbid with affective disorders), but they are less common than among younger suicides (see Conwell & Brent, 1995, for a review; Henriksson, Marttunen et al., 1995). Although differential mortality could be an alternative explanation for the lower rates of substance use disorders among older adult suicides, this would not explain the higher rates of affective disorders. As Conwell and Brent (1995) concluded, since affective disorders are less prevalent in late life but more common among older completed suicides, older adults who are depressed seem to be at higher risk of suicide than depressed younger adults.

7.09.6.4 Hopelessness

Hopelessness has been studied extensively as a possible correlate of suicide. Hopelessness has been linked to suicidal ideation (Wetzel, Margulies, Davis, & Karam, 1980) and completed suicides (Beck, Steer, Kovacs, & Garrison, 1985; Fawcett et al., 1990).

7.09.6.5 Issues in Late Life Suicide

A growing literature has documented the phenomenon that older adults who commit suicide frequently have seen a physician within a short interval before the suicidal death. In psychological autopsy studies of older adult suicides, Conwell et al. (1991) found that 75% had seen their physician within a month of the suicide. Takahashi et al. (1995) found that older adult inpatients on a psychiatric ward who were admitted after a suicide attempt were three times more likely to have seen a physician within the previous two weeks than older psychiatric inpatients who had not made a suicide attempt.

Another important issue concerns suicide among the medically ill. Suicides in this population have been described as rational, particularly in the presence of chronic pain or a poor prognosis (Battin, 1991). Although few studies have explored suicidal behavior in chronic or terminally ill individuals, the existing research indicates that depressive disorders are prominent in these cases (Henriksson, Isometsä, et al., 1995; Leibenluft & Goldberg, 1988). This result highlights the need to assess carefully for affective disorders and for suicide risk in medically ill individuals. Since pain has been associated with depressive disorders (Parmelee et al., 1991), effective treatment of pain may be an avenue for reducing both depression and suicide risk among medically ill older adults.

7.09.6.6 Assessment and Treatment

Assessment of suicide risk in older adults is an inexact science. Although older adults are at highest risk of suicide, most suicide research has focused on younger populations. There is ample reason, however, to doubt that findings would necessarily translate to an older suicidal population. As discussed earlier, older adult suicides differ in several important ways from younger suicides, including a higher degree of lethality and decreased likelihood of expressed suicidal ideation. There are no widely accepted assessment instruments validated with older individuals (for approaches to suicide risk assessment in this population, see Wolfe, Morrow, & Frederickson, 1995).

Even less research is available on the efficacy of interventions for suicidal older adults, or indeed for suicidal individuals of any age. In the absence of such information, the most promising approach in working with suicidal individuals with affective disorders is the effective treatment of these affective disorders.

7.09.7 COURSE OF DEPRESSION

In monitoring the course of depression, individuals can be classified as recovered (partial or full remission), relapsed, or chronic (nonremitted). Some have suggested that older adults show worse prognosis both in terms of lower rates of recovery and greater chance of relapse, but differences in study designs or sample characteristics make alternative explanations replete. When the differences are controlled, age in and of itself seems to have little prognostic value. Hinrichsen (1992) examined recovery and relapse rates in elderly depressed inpatients and compared them with those observed in a mixed age sample, using the same diagnostic and follow-up methods and the same uncontrolled treatment approach. He found that the rates were comparable: by one year after hospital admission, 59% of the elderly individuals achieved full or partial sustained recovery, 13% recovered and subsequently relapsed into the same condition as the index episode, and 28% never recovered. The figures for the mixed age sample were 58%, 16%, and 26%, respectively.

Kennedy, Kelman, and Thomas (1991) examined factors that contributed to chronicity, remission, and emergence of depressive symptoms in elderly community residents. Baseline health status was less predictive than change in health. Declining health and increasing disability were associated with chronicity, whereas improved health was associated with remission. This association could reflect a psychological reaction to decline or a more general wearing down process.

Diagnosed depression and depressive symptoms are associated with increased risk of mortality in institutionalized and inpatient samples (Evans, 1993; Parmelee, Katz, & Lawton, 1992) and in community residents (Thomas, Kelman, Kennedy, Ahn, & Yang, 1992). However, the explanation remains unclear. For example, the increased mortality may be related to the presence of cognitive impairment, that is, a comorbid dementia (Snowdon & Lane, 1995).

Burvill and colleagues examined mortality rates in a cohort of elderly depressed inpatients at the time of the index depressive episode, one year later, and then at five years (Burvill & Hall, 1994). Poor outcome of the index episode after one year (i.e., "depressive invalids" who had moderate symptoms of depression but not enough to merit diagnosis of major depression, continuously ill, or demented) was associated with increased mortality over the subsequent four years. Individuals most at risk of death were those who, on entry into study, were male, aged 75 years or older, had a diagnosis of major depression without melancholia or psychosis, and had substantial health and mobility problems.

Evans (1993), in contrast, found that one year death rates of depressed patients 12 months after inpatient treatment did not differ significantly from those of psychologically well individuals. Only timing of deaths varied, with most deaths occurring in the first three months for depressed individuals compared to being evenly distributed in the nondepressed group.

7.09.8 TREATMENT APPROACHES

The array of treatments provided to depressed older adults largely parallels those used to treat depression in adults generally. These can be divided into psychosocial treatments, predominantly psychotherapy, and somatic treatments, that is, psychopharmacological treatments and electroconvulsive therapy (ECT). There do appear to be some age differences in the distribution of treatments. For example, psychosocial interventions based on life review or reminiscence are exclusive to older adults. ECT has registered an increase in its use, disproportionately accounted for by older adults (Warren & Levy, 1991).

The literature is just beginning to have sufficient information to give good guidance. In the past, studies have not always distinguished between treating a disorder and endeavoring to raise scores on depression self-report scales for community volunteers who were not necessarily depressed to begin with. In fact, this failure may contribute to a misperception perpetuated by the Consensus Development Conference Statement (Friedhoff, 1994) that psychotherapy is for mild (nonserious) depression, while somatic treatments are for true depression. Because the topic of the chapter is mood disorders, for the purposes of discussing efficacy of treatment, the focus is on studies with individuals who have a diagnosed disorder. However, to reflect interest in variations of disorder observed in older adults, literature concerning subdysthymic disorder is included.

7.09.8.1 Psychotherapeutic Interventions

Psychosocial treatments for depression encompass psychodynamic psychotherapy, brief psychodynamic therapy, interpersonal therapy, behavior therapy, cognitive and cognitive behavior therapy, life review, marital and family therapy, and group therapy (which can be psychodynamic or cognitive-behavioral). Empirical evidence to date suggests that efficacy of treatments for older adults is basically similar to efficacy for adults generally. However, the fact that older adults are not routinely included in evaluations of interventions is disturbing, for example, the Treatment of Depression Collaborative Research Program (Elkin et al., 1989).

There are several available reviews of psychological treatments for depression, including Scogin and McElreath's (1994) meta-analysis and chapters by Futterman, Thompson, Gallagher-Thompson, and Ferris (1995), Niederehe (1994), Smyer, Zarit, and Qualls (1990), Teri, Curtis, Gallagher-Thompson, and Thompson (1994), and Wolfe, Morrow, and Frederickson (1995). Clinical psychologists have placed more explicit attention on identifying those interventions that are supported empirically, and on establishing criteria by which to make this judgment (Chambless et al., 1996; Gatz et al., in press). While not directly employing this framework, treatments that are supported by good empirical designs are emphasized (e.g., randomized controlled trial).

7.09.8.1.1 Cognitive-behavior therapy

The rationale for behavioral therapy for depression is found in Lewinsohn, Muñoz, Youngren, and Zeiss (1996), and the rationale for cognitive therapy in Beck, Rush, Shaw, and Emery (1979). Behavior therapy teaches the role of reduced reinforcement in creating and maintaining depression, methods to increase pleasant events, relaxation techniques (Bernstein & Borkovec, 1973), and problem-solving skills (Nezu, Nezu, & Perri, 1989). Cognitive therapy teaches the importance of negative, pervasive attributions about oneself, the world, and the future in determining one's mood, and offers methods to monitor and challenge these thoughts. In both cases, the treatment was developed for adults in general. In studying the effectiveness of these therapies, sometimes the two are contrasted with one another; sometimes a combined cognitive-behavioral therapy is compared with another treatment. In practice, it is probably most common to combine elements of both behavioral and cognitive treatments, and the outcome research does not lead us to differentiate among these approaches.

Adaptations for older adults include changing pleasant events lists to be more appropriate to the activities in which older adults are likely to engage and resolving practical barriers such as mobility and vision limitations (Rybarczyk et al., 1992). These adaptations seem unlikely to interfere with comparisons of treatment outcome across age groups.

Gallagher and Thompson have conducted a series of studies that provide the clearest evidence for the efficacy of cognitive and behavioral treatments for patients meeting diagnostic criteria for major depressive disorder. The first study (Gallagher & Thompson, 1982) compared individual cognitive, behavioral, and supportive/insight therapy; the second (Thompson, Gallagher, & Breckenridge, 1987) compared individual cognitive, behavioral, and brief dynamic therapy with a waiting list control group also included in the design. Treatment lasted 20 sessions. At post-test, all therapies registered improvement on self-report and observer-rated scales and on proportions of patients diagnosed as depressed; all therapies were more effective than the control group. At follow-up assessment a year after termination of treatment, in the first study, maintenance of gains was superior for the behavioral and cognitive groups compared with those who had received supportive/insight therapy (Gallagher & Thompson, 1983). In the second study, there was no difference among treatments (Gallagher-Thompson, Hanley-Peterson, & Thompson, 1990).

Two other research groups have included psychopharmacological conditions, but permit evaluation of the psychotherapy component. Beutler et al. (1987) compared various combinations of cognitive therapy and alprazolam (Xanax). Cognitive therapy was administered in small groups. All four groups (including the placebo) improved on both BDI and HRSD. The placebo group and the medication-only group showed less steep improvement on the BDI and a reversal to baseline levels at follow-up.

Steuer et al. (1984) compared cognitive-behavioral to psychodynamic psychotherapy administered in groups. Participants had volunteered for a drug study (Jarvik, Mintz, Steuer, & Gerner, 1982), and psychotherapy groups were by and large filled by those for whom pharmacologic treatment was contraindicated due to a chronic physical disease or to a medication being used to treat such a condition. Periodic assessments over the nine months of psychotherapeutic treatment showed significant improvement on self- and observer-rated scales for both modalities. On the BDI, cognitive-behavioral treatment was superior to psychodynamic. Riskind, Beck, and Steer (1985) used Steuer et al.'s data to demonstrate that nearly 50% of the cognitive therapy patients were either in remission or only mildly depressed at the conclusion of treatment.

These studies have not been replicated by large numbers of other laboratories. Campbell (1992) found significant reductions in depression after individual cognitive therapy combined with reminiscence in comparison with a psychological placebo (a crafts group) and to an untreated control group. Improvement was measured with the Zung SDS and with thought diaries. Arean et al. (1993) compared problem-solving group therapy, group reminiscence therapy, and a waiting list control group. Individuals in both the problem-solving and reminiscence group showed reductions in depression (assessed with HRSD, BDI, GDS) in comparison with the control group, with extent of improvement at post-test and maintenance of gain better for the problem-solving therapy than for reminiscence. Problem-solving therapy was also applied successfully by Hussian and Lawrence (1981) with mildly to severely depressed nursing home residents.

All of these outcome studies had similar exclusion criteria: nonsuicidal, nonpsychotic, no cognitive impairment, or alcohol abuse. In addition, many potential participants with chronic physical illnesses were *de facto* excluded because these studies typically relied on community samples who could come to the facility where treatment was being administered. However, it should not be concluded that depression was not severe. For example, in Thompson et al. (1987), mean BDI was 23.5 at pretest; mean HSRD was 19.1. In Beutler et al. (1987), mean HSRD at pretest was 22.0 across all groups, mean BDI (on the 13-item form) was 11.3. In Steuer et al. (1984), mean BDI (on the 13-item form) was 15.3; mean HSRD was 18.7.

Dropout rates are not always easy to discern from published descriptions. Thompson et al. (1987) report that they had four patients drop out of behavioral (14%), four from psychodynamic (14%), and 10 from cognitive therapy (27%). Dropping out reflected expressed dissatisfaction or more ambiguous causes, such as the client's declaring transportation problems or physical illness. Beutler et al. (1987) reported dropout at 13% in the first four weeks; thereafter, it was 67% for medication and 31% for cognitive therapy, with or without medication. Side effects of the drugs was a key factor for most. Steuer et al. (1984) found dropout rate to be 39% across both types of psychotherapies, with no difference between them, but only 9% before the 12th week.

7.09.8.1.2 Brief psychodynamic, interpersonal, and life review therapies

Brief psychodynamic and interpersonal therapies have resulted in a clinical literature describing special aspects of their application to older adults. For interpersonal therapy, a manual has been prepared for older adults (described in Reynolds et al., 1992). The most salient difference is in the nature of the interpersonal problems. Life review traces its conceptual roots to Erik Erikson's description of the eighth stage in the life cycle, where the individual deals with the achievement of ego integrity. Butler (1974) has provided a framework for making this task more intentional and more therapeutic. There is no comparable therapy for younger adults.

Thompson et al. (1987), Gallagher and Thompson (1982), and Steuer et al. (1984), already described, all showed brief psychodynamic therapy or supportive/insight therapy to be generally equivalent to cognitive-behavioral approaches, sometimes not on all measures or after extended follow-up. Schneider, Sloane, Staples, and Bender (1986) found interpersonal therapy (IPT) to be as effective as nortriptyline and superior to placebo control, indicated by 58% improvement on HDRS for drug and 64% for psychotherapy; in addition, dropout rate was lower for IPT than for medication.

Reynolds et al. (1992) tested the efficacy of IPT combined with nortriptyline, IPT alone, nortriptyline alone, and placebo as a maintenance treatment for depression. Participants were older adult patients who had already been treated in the acute and continuation phases by combined IPT and nortriptyline. No one started maintenance treatment unless they had already improved. Of patients who began the study, there was 19% attrition before the end of the continuation phase, and 16% of those who completed treatment did not improve. Preliminary results showed that 24% of those shifted to placebo suffered relapse, with no significant difference for those in IPT or not in IPT.

A variant of IPT, interpersonal counseling (IPC), has also been used with subsyndromal dysthymia. Mossey et al. (1996) compared IPC to usual care for recently discharged medical patients with GDS scores in excess of 10 at two occasions before treatment began, but who did not meet diagnostic criteria for major depressive disorder. Follow-up at 2–3 months after completing 10 sessions of IPC indicated that those receiving IPC had significantly lower depressive symptoms than the control group.

Fry (1983) compared life review to unstructured reminiscence and found both superior to an attention placebo. Haight (1992) compared reminiscence, using structured life review devised by the author to standardize the intervention, to a friendly visitor program (attention control) and to a no-treatment group. She found improved psychological well-being that was maintained at follow-up but no significant change on Zung SDS. In neither of these studies were *DSM* diagnoses used to screen participants. Haight's sample was homebound and therefore assumed to be at elevated risk of depression.

With participants diagnosed with major depressive disorder, Arean et al. (1993), as has been described, found life review superior to a waiting list control but not to problem-solving therapy. In a nursing home sample, Dhooper, Green, Huff, and Austen-Murphy (1993) found a combined life review and problem-solving group superior to a control group, with depression measured with the Zung SDS. Niederehe (1994) cautions not only has most of the research on life review been conducted with minimally symptomatic samples, but also the technique could have negative effects with individuals who do have major depressive disorder.

7.09.8.1.3 Support groups and psychoeducational interventions for depression in caregivers of dementia patients

A population that has received special attention are caregivers of older adults, especially of older adults with AD. As noted already, caregivers are subject to increased risk of depression as well as more general strain and burden. Moreover, depression often accompanies dementia; thus, both the older adult with dementia and the caregiver are appropriate targets for treatment.

A meta-analysis of interventions for caregiver distress (Knight, Lutzky, & Macofsky-Urban, 1993) concluded that these interventions did have a respectable effect on mood and burden. Although outcome measures often include measures of depression, participants do not always meet criteria for depressive disorder. Elements of intervention with caregivers typically include emotional support and sharing of common experiences, training in problem solving and stress reduction, and education about the disease and community resources. The component concerned with problem solving and stress reduction tends to build on a behavioral model of treatment for depression. Using this framework, for example, Gallagher-Thompson (1994) developed a treatment manual and curriculum, called "Coping with the Blues." She and her colleagues reported significant reduction of depression on the BDI (Lovett & Gallagher, 1988).

An additional element is added by Teri, Logsdon, Wagner, and Uomoto (1994), whose model is to involve both the caregivers and dementia patients. The intervention explicitly teaches the caregivers to use a behavioral model with the dementia patient, focused on the role of pleasant events in maintaining a positive emotional state.

7.09.8.2 Pharmacological Interventions

The most common psychopharmacological treatment for depression in older adults has been the tricyclic antidepressants, amitriptyline (Elavil), imipramine (Tofranil), desipramine (Norpramin), protriptyline (Vivactyl), and nortriptyline (Pamelor). Tricyclics all have anticholinergic side effects, related to degree of muscarinic blockage, manifesting both centrally (delirium, confusion) and peripherally (urinary retention, tachycardia, orthostatic hypotension). The older drugs in this category, such as amitriptyline and imipramine, have more severe side effects, while nortriptyline is regarded as perhaps causing the least orthostatic hypotension, and desipramine is least anticholinergic (Jenike, 1989; Salzman, 1994). Age-related changes in drug metabolism by the liver and in neurotransmitters may also lead to greater sensitivity to both therapeutic and side effects (Naranjo, Herrmann, Mittmann, & Bremner, 1995). The effect of concurrent medications can also be substantial (Reynolds, Schneider, Lebowitz, & Kupfer, 1994). The reason that orthostatic hypotension is a concern lies in risk of falls. One report suggests that risk of hip fracture is tripled by the use of tricyclic antidepressants (Ray, Griffin, Schaffner, Baugh, & Melson, 1987). Cardiac side effects are also a concern (Glassman & Roose, 1994).

Newer, or second-generation, antidepressants with atypical structure, such as trazodone (Desyrel), may be especially sedating although having fewer anticholinergic effects and cardiac side effects. Other newer medications are selective serotonin-reuptake inhibiting (SSRI) antidepressants, for example, fluoxetine (Prozac) and sertraline (Zoloft). These do not have the same cholinergic side effects as tricyclics, however, their cardiac side effects have not received sufficient study (Reynolds et al., 1994). It has been reported that substitution of SSRIs for tricyclics is occurring at a slower rate for patients aged 65 years and older than for patients younger than 65 years (Klawansky, 1994), although the picture may be changing and different settings may have different prescribing habits.

Monoamine oxidase inhibitors also present side effects, including orthostatic hypotension (Naranjo et al., 1995). Lithium, which is commonly used to treat bipolar disorder, requires particularly careful regulation of dosage in older adults, and creates a particular risk of neurotoxicity when the patient is demented (Jenike, 1989).

In their review of drug studies through 1986, Gerson, Plotkin, and Jarvik (1988) conclude that remission rates on the HRSD among those with major depressive disorder averaged 51% across different drugs, predominantly tricyclic antidepressants, with no obvious advantage for one drug over another. This contrasts with a mean improvement of 20% for those on placebo. Dropout rates were 19% for those in the active drug conditions and 31% for those in the placebo condition (average = 21%). Side effects were described as a major impediment.

Klawansky (1994) collected all available randomized controlled trials through 1991 for meta-analysis. Drugs were more effective than placebo and also had more side effects. There was no overall difference in dropout rates between tricyclics and placebo. Those on medication mainly dropped out because of side effects and those in the placebo condition, due to lack of benefit. In comparisons of fluoxetine to tricyclics, dropout was less for those assigned to the fluoxetine condition.

As with psychotherapeutic studies, psychopharmacologic studies tend to feature time-limited treatments and to exclude patients who have various complications. By default, those excluded are often the oldest patients. There is almost no literature on patients aged 80 years and older (Salzman, 1994). In these respects, research may match poorly with actual practice. Thus, it is of interest to look at Katz, Simpson, Curlik, Parmelee, and Muhly (1990), who conducted a double-blind study of nortriptyline with nursing home and congregate housing residents. After excluding those who had contraindications (22%), or refused, or met some other exclusion criterion, patients who completed the drug treatment improved significantly on the HRSD but not on the GDS relative to the placebo control group. Still, of patients given active medication, 11 of 32 (34%) had some sort of adverse event, acknowledging that it is impossible to accurately distinguish side effects from unrelated medical events. Nortriptyline has also been studied with patients who have both depression and dementia (Salzman, 1994), a group for whom cognitive side effects are a particular concern.

Comparisons of pharmacotherapy to psychotherapy are limited. In Jarvik et al. (1982), although assignment to drug and to psychotherapy was not random, the authors note that (i) more patients dropped out of the drug conditions than group therapy, (ii) improvement for psychotherapy tended to be more homogeneous, while improvement for the drug conditions was bimodal, with patients either responding or failing to respond, (iii) group therapy was significantly more effective than placebo drug. Given the concern with side effects among older adults, the recommendation of Wexler and Cicchetti (1992) seems sensible; that is, begin with psychotherapy, and if it is not effective, add medication.

7.09.8.3 Electroconvulsive Therapy

Treatment with electroconvulsive therapy (ECT) is attractive when side effects of medications are of particular concern or the patient has not responded to medication, or when there is particular urgency. Many argue that ECT is actually safer than drugs. The short-term efficacy of ECT with older adults is well accepted (Sackheim, 1994). Relapse does tend to be high, which has led to studies of continuation and maintenance ECT (e.g., Zorumski, Rubin, & Burke, 1988). While drugs are used commonly to prevent relapse after ECT, the same reasons for not turning to drugs in the acute phase would also be applicable when considering drugs for this role.

Rate of complications does increase with age, although ECT is used in those over age 80 years (Cattan et al., 1990). The main side effects are cardiovascular, with these complications generally accounting for ECT-related mortality. Cognitive side effects are a major concern, including the fact that confusion can lead to falls. Brief confusion directly after treatment is standard. Duration of amnesia varies. Severity of cognitive sequelae appears to be related to mode of administration. It is also not established whether those who already have cognitive dysfunction are particularly at risk of cognitive complications, especially lasting or severe effects, if their depression is treated with ECT. However, ECT is used in mixed depression and dementia (Liang, Lam, & Ancill, 1988).

While ECT advocates argue that the treatment is underused, there are three other implications of this literature. First, improved recognition of depression could lead to its earlier treatment, so that cases do not take on the urgency that more often results in referral for ECT. Second, since side effects do seem so dependent on technique, monitoring of side effects and relapse is advisable not only in controlled trials in academic clinical centers, but also at sites where ECT is often administered, such as private not-for-profit and private for-profit hospitals (Sackheim, 1994). Third, treatments to prevent relapse should incorporate more psychotherapy and more environmental manipulation, including work with the family and social networks.

7.09.8.4 Concluding Comment

It is difficult to discuss treatment without also discussing problems in getting the older adult to treatment (Estes, 1995). Older adults tend to be seen by a primary care physician who either does not notice depression or elects not to treat it. The older adult may contribute by failing to seek treatment for symptoms of depression, or by not mentioning the symptoms to the primary care physician. Reasons suggested for failure to recognize depression include: comorbidity with physical health problems, which become the focus of treatment; lack of training in geriatrics; older adults' reticence to discuss emotional distress; older adults' attribution of the symptoms to normal aging. As a consequence, much depression may go untreated, may not be treated until it becomes severe, or may be mistreated, for example, with anxiolytics or with sleeping pills, until it becomes severe and gives the false impression of intractability and hopelessness. If the depression is recognized by the primary care physician, it may be easiest to treat it with drugs, like the patient's physical conditions are being treated, particularly because the depression may have notable somatic manifestations. Referral to specialists is uncommon. Because of delays in initiating treatment, by the time that treatment is begun, the depressed older adult may more often seem like a psychiatric emergency, posing a danger to him or herself explicitly via creating fears of suicide or implicitly by extreme lack of self-care (e.g., not eating). These delays are combined with a greater background chance of physical frailty, so that the individual may not be physically as capable of enduring an episode of depression. This systemic context may lead to greater emphasis on somatic solutions.

7.09.9 PREVENTION

Prevention of depression is of keen interest because research results about risk and protective factors can inform preventive intervention strategies. Risk and protective factors, both established and putative, are suggested by the literature on correlated and etiological influences. In turn, this literature betokens key points of intervention for any preventive efforts.

The Institute of Medicine (Mrazek & Haggerty, 1994) recommends distinguishing universal, selective, and indicated preventive measures. Indicated interventions are directed toward individuals who may have symptoms that foreshadow disorder or some kind of marker that may indicate a predisposition. Selective preventive interventions are targeted to subgroups who may have an elevated risk. Universal measures are targeted to the general public. These distinctions can usefully be applied to older adults (Smyer, 1995).

7.09.9.1 Indicated Preventive Measures

Screening and outreach are core tools for indicated preventive intervention. One of the best indicators of risk of future depression is depressive symptoms. Using Epidemiologic Catchment Area survey data, Horwath, Johnson, Klerman, and Weissman (1992) demonstrated that incidence of first-onset major depression was significantly increased in individuals who reported depressive symptoms when interviewed the previous year. Indeed, over half of new cases of major depression were associated with a history of depressive symptoms. These findings provide a strong empirical rationale for depression symptom screening, for example, national depression awareness days.

Unfortunately, screening for depression, especially in older adults, is not practiced widely. Dorfman et al. (1995) used a computer-assisted questionnaire with depression items from the CES-D supplemented by a second instrument. Among a sample of generally healthy community-dwelling adults aged 65 years and older, they found that nearly three-quarters of those with major depression were not being treated. However, when these individuals were referred to a mental health professional, two-thirds did seek help. These results illustrate both the failure to screen, since these individuals had not heretofore been identified as having depressive disorder, and the fact that screening can be effective in getting people with significant distress linked to treatment.

The high rate of depressive symptoms and disorder among medical patients suggests that primary care practitioners are uniquely well positioned to conduct screening for depression. However, underrecognition of psychiatric conditions by primary care physicians in outpatient and inpatient settings is well demonstrated (Jorm, 1995; Rapp et al., 1988). In a sample of older individuals of Latino origin in Southern California, Kemp et al. (1987) found that none of the respondents who scored as depressed on the screening instrument reported receiving any treatment for depression. Notably, 90% had seen a physician within the past year, where there could have been an opportunity for screening to occur. Mann (1995) determined that primary care physicians were unaware of their patient's depression in two out of every three cases where the patient was in fact pervasively depressed. The pivotal role of the primary care practitioner is further supported by evidence that some three-quarters of elderly persons who kill themselves have recently seen a physician (Conwell et al., 1991).

These observations have led to strong recommendations that health service providers be trained to screen for depression as a condition of licensure or certification (White House Mini-Conference on Emerging Issues in Mental Health and Aging, 1995). Methods for improving the recognition of depression by primary care physicians have been evaluated, including visits to the physician's office analogous to visits by drug industry representatives, during which the physician is presented with a list of questions to use in making a diagnosis (Pond, Mant, Kehoe, Hewitt, & Brodaty, 1994).

Outreach programs to older adults aim to make it easier for the older adult who does have symptoms of depression to connect with someone who can offer assistance. Waters (1995) emphasizes the use of alternative settings, not only health care clinics, but also neighborhood centers, senior centers, religious institutions, community organizations, educational institutions, as locations where mental health care is available. Raschko (1985) established the Gatekeepers program, in which he trained meter readers, letter carriers, bank tellers, and others who might have contact with older individuals who lived alone, so that they became referral sources.

Once individuals with symptoms of depression are identified, Horwath et al. (1992) caution that most will not go on to become clinically depressed. Therefore, these authors suggest, it would be premature to use antidepressant medication to treat depressive symptoms. There may also be reluctance to see a mental health professional. Thus, Breckenridge, Zeiss, and Thompson (1987) developed a nine-week Life Satisfaction Course for older adults who have depressive symptoms but do not meet criteria for major depression. The course is built on Lewinsohn's psychoeducational model (Lewinsohn et al., 1986). This group (Thompson, Gallagher, Nies, & Epstein, 1983) has also offered Coping with Depression classes for older adults, targeted towards those who were clinically depressed. Participation in these classes resulted in improvement on measures of depression and life satisfaction.

7.09.9.2 Selective Preventive Interventions

Selective interventions are directed toward subgroups who have an elevated risk of depression. Research on risk factors for depression suggests what some of those subgroups may be. Phifer and Murrell (1986) found that an increase in CES-D scores from below 16 to 20 or higher was predicted by depressive symptoms six months earlier, poor health, loss events, and low social support, with support functioning both additively and interactively. In the Western Collaborative Group Study of older men, increase on the CES-D was predicted by poor perceived health and stroke, while physical exercise was protective (McElroy, Carmelli, Swan, & LaRue, 1995). It is often observed that the rate of mood disorders in stroke patients is high, and that depression can interfere with cognitive and functional recovery.

A major loss event is spousal bereavement. One of the best known prevention programs is "Widow-to-Widow," developed by Silverman (1969) and sponsored by the American Association of Retired Persons (AARP). Vachon et al. (1980) showed, in a controlled study, that fewer depressive symptoms were experienced by program participants than by the control group. Vachon and Stylianos (1988) have suggested ways to identify which bereaved individuals may be at greater risk of distress based on the adequacy of their social support network, and they propose that friends and family of the bereaved could be taught to distinguish helpful from unhelpful methods of support.

Among medical patients, strategies to prevent depression can include treatment of pain and maintenance of good nutrition (Katz, Streim, & Parmelee, 1994). In cognitively intact or mildly demented patients admitted to long-term care facilities, it has been suggested that prevention of depression may be accomplished through fostering social support in the setting, maximizing opportunities for autonomy and control, and promoting coping skills with respect to institutional life (Foster & Cataldo, 1994). However, there is not good research on the effectiveness of psychotherapeutic interventions with the physically ill or with those in long-term care settings (Jorm, 1995).

A final typical target for selective preventive interventions are caregivers of demented or physically incapacitated older adults. Meta-analysis suggests that psychoeducational support groups are effective in alleviating burden (Knight et al., 1993).

7.09.9.3 Universal Preventive Interventions

Universal preventive programs include public education campaigns and various wellness programs (Waters, 1995). Prevention research programs under this heading present major methodological problems, particularly with respect to demonstrating decreased incidence of a specific mental disorder (Mrazek & Haggerty, 1994). A central consideration should be linking the knowledge base about risk and protective factors to educational strategies for older adults and those who work with them (Smyer, 1995).

7.09.10 CONCLUSION

Old age is not characterized by depression. When depression is experienced, the most frequent mood disorders seem to be those about which least is known. Some of the newer diagnostic categories or symptom clusters, that is, minor depression, depletion syndrome, hopelessness depression, are promising descriptors.

Gerontological literature often blurs the distinction between depression as a clinical entity and depression as an expression of negative affect and hence a convenient indicator of well-being in old age. This blurring may contribute to the misconception that depression is an inevitable accompaniment of aging, brought on by the various losses and indignities, and also by the conviction that depression is underdiagnosed among older adults. Blurring also occurs in the literature on prevention, where distinctions often are poorly drawn between programs to augment well-being and programs where prevention of mood disorder is legitimately realized.

Stress does predict depression. Yet, despite the chronic illnesses and psychosocial strains that frequently distinguish old age, most older people manage without becoming depressed. Physical illness and cognitive dysfunction are major correlated factors for depression in old age. These factors help to account for age differences in presentation and appear to be of etiological significance. For example, there may be a general wearing down process underlying depression, physical symptoms (often cardiovascular), and functional decrements. For late-onset depression, with no previous episodes at younger ages, the depression often foreshadows dementia. Depression in old age also has important consequences with respect to both morbidity and mortality.

Numerous assessment instruments are available, with relative levels of use and sanction not necessarily reflective of existing empirical evidence as to measurement efficiency. The problems with depression scales reflect the nature of depression in old age, that is, the need to evaluate syndromes other than major depression and issues of differentiating depressive disorders among those who are physically or cognitively frail.

Although suicide is a relatively rare event, and most people who are depressed do not commit suicide, the risk of a completed suicide is highest in old age. This is an area where proper assessment and intervention can make a difference.

Psychotherapy works rather well with older adults, and there is empirical and practical guidance available about the best approaches. Somatic approaches have been overemphasized in the treatment of depression in late life. Although they appear to be effective for acute treatment, evidence is not unambiguous that they are more effective than psychotherapy. The guideline that psychopharmacology should be used with severe depression while psychotherapy should be used with mild depression does not accurately reflect the research. In studies of both drugs and psychotherapy, the patients tend to be young old, less physically ill, and more compliant. Risks of pharmacotherapy are higher in older individuals due to greater likelihood of comorbid medical conditions, greater likelihood of interaction with other medications, and greater sensitivity to dosage levels. Moreover, somatic treatments have no lasting effect on dysfunctional thoughts and nonhelpful or depopulated social networks. There is need for evaluations of combined treatments that reflect actual clinical practice, greater attention to dropouts and those who relapse, and studies of depressed patients with concurrent medical conditions. Better outreach and early assessment can also reduce the need for urgent intervention.

Finally, promising approaches to prevention of depression among older adults lie in training those in a position to screen for symptoms, targeting the most vulnerable segments of the older population, and disseminating knowledge about risk and protective factors.

7.10.1 INTRODUCTION

Several reviews agree that Alzheimer's disease (AD) results in a global cognitive impairment that involves deficits in perception, attention, psychomotor speed, memory, visuospatial functioning, intelligence, and language (Bäckman, 1992; Morris, 1996; Nebes, 1992).

This extension of cognitive impairment in AD is to be expected, given that this disease is associated with marked lesions in limbic structures as well as in the neocortical association areas (Braak & Braak, 1991, 1995; Frackowiak et al., 1981; Grady et al., 1990; Haxby et al., 1990).

However, the view that AD affects our cognitive functions in a global manner does not necessarily imply that all functions decline at the same time and at the same rate. By contrast, some variability in the degree to which different cognitive functions are compromised should be expected, given that (i) the neuropathological trajectory in AD may begin with lesions in medial-temporal regions that gradually radiate into neocortical (e.g., temporal, parietal, and frontal) areas (Braak & Braak, 1991, 1995; Fewster, Griffin-Brooks, MacGregor, Ojalvo-Rose, & Ball, 1991); and (ii) different cognitive tasks vary with regard to the extent to which overlearned skills, procedures, and knowledge could be utilized. Conceivably, this variability is likely to decrease as a function of increasing severity of dementia. Knowledge regarding whether AD related cognitive deficits occur in a lawful manner across the pathogenesis would seem to be imperative not only for advancing our scientific understanding of the disease itself, but also to facilitate early clinical diagnosis and be useful in behavioral intervention.

The purpose of this chapter is to provide an overview of recent research addressing the aforementioned issues. The overview is organized so as to parallel the disease development. That is, we begin by reviewing the evidence pertaining to potential preclinical cognitive markers of AD. This is followed by an examination of the cognitive tasks that may or may not be useful in differentiating early AD patients from normal old adults. The next step is to determine whether the same cognitive tasks that are particularly effective at detecting AD are also most sensitive in discriminating between patients at different phases in the disease process.

Most of the work examining the efficacy of cognitive measures in detecting and staging AD is cross-sectional in nature; this is reflected in the present review. However, an increasing number of longitudinal studies charting the cognitive progression in AD are available. Examining the results from these studies not only allows for an interesting comparison with the cross-sectional research on detection and staging of AD but also it provides the necessary means by which different cognitive functions can be compared with regard to rate of pathological change.

Although a major goal of the chapter is to examine whether there is a predictable development of cognitive decline in AD, there may also be individual differences among patients with regard to both the magnitude and rate of change in various cognitive functions. Individual difference variables (e.g., demographic, psychometric, biological) have been found to be powerful mediators of cognitive performance in normal aging (e.g., Elias, Wolf, D́Agostino, Cobb, & White, 1993; Wahlin et al., 1993; West, Crook, & Barron, 1992). Thus, an additional objective of this chapter is to determine whether variability in cognitive performance among AD patients can systematically be linked to specific subject-related factors.

Before describing the changes in cognitive performance that accompany AD, it is important to address a number of practical problems associated with studying this population of individuals. The most basic problem concerns the uncertainty of the diagnosis itself. Although the diagnostic criteria in the last few years have become increasingly strict (American Psychiatric Association, 1980, 1987, 1994; McKhann et al., 1984), there are still no specific clinical diagnostic markers for AD. Presently, the clinical diagnostic criteria are descriptive and exclusive, and pathological confirmation remains the current "gold standard" for AD diagnosis (Galasko et al., 1994; Huppert, Brayne, & O'Connor, 1994). Unfortunately, in AD research most studies have relied on the clinical diagnosis as the gold standard, which means that the criterion variable is far from perfect. It is possible that the clinical diagnostic criteria are not sensitive enough to detect very old subjects in a very early phase of AD. For example, what defines normality (e.g., in terms of physical, sensory, and cognitive status) may be rather equivocal in very advanced age (Brody & Schneider, 1986; Fries & Crapo, 1981), making diagnostic decisions uncertain (e.g., Fratiglioni, Grut, Forsell, Viitanen, & Winblad, 1992). Nevertheless, because these clinical criteria are one of the only means, at the present time, for rendering dementia diagnoses we must utilize what is available to us.

In addition to problems associated with dementia diagnosis, there are a number of issues regarding sample composition, such as sample selection, sample size, and dementia etiology that require consideration. These three facets all have the potential to influence the results that are found from studies that have examined cognitive performance in demented persons. The following section addresses these aspects of sample composition.

7.10.2 SAMPLE COMPOSITION

The source from which researchers select their populations of demented and nondemented (control) subjects has important implications for the severity of impairment that is observed, as well as the extent to which the results that are produced are generalizable to the population of adults at large. Typically, samples of demented and nondemented subjects are selected from clinical or population settings. One of the advantages of selecting patients from a clinical setting is often that relatively large numbers of subjects are available for study. Further, the accuracy of the dementia diagnosis is likely to be more precise, because clinicians are allowed to spend more time interviewing the patient and relevant family members as compared to population-based studies (Brayne et al., 1995). In addition, various diagnosis-related assessment procedures, including radiological assessment (e.g., computerized tomography, magnetic resonance imaging) as well as other medical procedures (e.g., blood sampling) are easier to implement in a clinical setting, thus enhancing diagnostic accuracy. Alternatively, there are also several disadvantages in selecting subjects from clinical populations. For example, it is likely that these subjects are biased towards being more demented than subjects from the community. In addition, the controls used in a clinical setting are likely to be healthier and cognitively superior compared with a random sample from the community. Both of these factors may result in an overestimation of the differences between patients and controls. Moreover, the greater initial impairment of the clinical population may make investigating mild changes in dementia difficult, because these populations are dominated by persons with more obvious signs of cognitive deficiencies. This may have negative repercussions concerning the generalizability of the findings that are observed. That is, when individuals self-select themselves for assessment in a clinical setting, the composition of this group, both demographically and cognitively, may be very different from studies who use patients that are sampled in a more representative fashion.

One of the chief advantages of sampling adults from the community is the ability to make generalizations back to the larger population. In addition, more diversity in terms of cognitive performance and demographic characteristics may be present in the samples as compared to clinical populations. This diversity is represented not only as milder levels of impairment among the demented subjects, but also in terms of increased variability in performance among those who are nondemented. Although there are benefits in examining cognitive performance in community-based samples of adults, there are also several disadvantages. Chief among them is the small sample size of demented adults that is often available. The relatively small sample size of demented persons in population-based studies is largely a byproduct of prevalence and incidence rates of AD. Several studies have shown that between 1.3 and 11.2% of adults over the age of 65 have AD (see Ebly, Parhad, Hogan, & Fung, 1994, for a review). Although prevalence rates increase with age, it remains that the population that must be sampled to achieve sufficient numbers of AD patients needs to be relatively large. Similar problems of small sample sizes are evident in studies that have examined incidence of dementia (e.g., Katzman et al., 1989; Tierney et al., 1996).

To combat problems with small sample sizes of AD patients, some authors have resorted to combining different dementia etiologies, typically AD and vascular dementia (VaD), into one group (e.g., Almkvist & Bäckman, 1993a, Herlitz, Hill, Fratiglioni, & Bäckman, 1995; Small & Bäckman, 1996). Although this procedure does reduce problems associated with sample size, it can be criticized on the grounds of potentially obscuring relationships with cognitive performance because of the different dementia types. For example, Gottfries, Blennow, Wallin, and Gottfries (1995) found that AD and VaD patients significantly differed in a number of cognitive dimensions. Specifically, on the one hand, AD patients experienced more parietal symptoms (e.g., sensory aphasia, visuospatial dysfunction), whereas VaD patients experienced more symptoms related to confusion (e.g., clouded consciousness, attentional problems) and subcortical impairments (e.g., psychomotor retardation). However, there is a growing body of evidence indicating nearly identical patterns of cross-sectional performance in tasks assessing various aspects of episodic memory for those individuals with AD and those with VaD (e.g., Almkvist, 1994; Almkvist, Bäckman, Basun, & Wahlund, 1993; Erkinjuntti, Laaksonen, Sulkava, Syrjäläinen, & Palo, 1986). A reasonable recommendation is that studies utilizing more than one dementia type should incorporate a test of the differences between the groups in their analyses. Only after different dementia groups have been found to be indistinguishable in the measures of relevance, is collapsing across dementia etiology justifiable.

In this chapter, we review studies that have focused exclusively on subjects with AD, but also on studies that have combined different dementia etiologies. This has been done for purely pragmatic reasons; the pool of available studies is so much larger when accounts that have used both subject selection methods are employed. Nevertheless, we will orient the reader to the use of these different subject groups and, where possible, indicate whether between-group comparisons were made.

7.10.3 INCIDENCE OF DEMENTIA

A number of studies have examined potential preclinical cognitive markers of dementia. In these studies, subjects are followed longitudinally and incident cases of dementia are identified. Investigators then compare the baseline cognitive performance of these two groups of individuals to determine whether a certain profile of cognitive performance is predictive of who will develop dementia. Identifying certain patterns of performance that may be particularly diagnostic of future dementia status has important clinical implications. Persons may be identified relatively early in the disease process and appropriate behavioral or pharmacological therapies may be designed to best deal with the impending disease process. Further, supportive opportunities (e.g., support groups, day care arrangements) for family members can be developed in attempts to lessen the impact of the dementia on loved ones.

Several studies have investigated the relationship between baseline performance on global indices of cognitive functioning and dementia incidence (Aronson et al., 1990; Katzman et al., 1989; Yoshitake et al., 1995). These measures, such as the Mini-mental state examination (MMSE; Folstein, Folstein, & McHugh, 1975), the Mattis dementia rating scale (MDRS; Mattis, 1976), and the Blessed information-concentration test (BIMC; Blessed, Tomlinson, & Roth, 1968) are designed to index a person's global level of cognitive performance. In general, research indicates that individuals who initially score at low levels on these cognitive indices are more likely to develop dementia than the remaining study sample. For example, Aronson et al. (1990) examined this relationship with the BIMC and found baseline performance on this measure to be a strong predictor of dementia incidence (AD, VaD, and mixed dementia). Similar results were reported by Yoshitake et al. (1995), whereby baseline performance on a Japanese test of global cognitive functioning, Hasegawa's dementia scale, was predictive of subsequent development of AD.

Although some investigators have focused on measures of global cognitive functioning as predictors of dementia incidence, others have examined specific aspects of cognitive performance. In these studies, larger batteries of cognitive tests, comprised of indices assessing domains such as episodic memory, visuospatial functioning, and verbal ability were administered at baseline. Among the specific measures of performance that have been found to be related to dementia incidence, evidence has indicated that markers of verbal ability, including the Boston naming test and measures of category fluency (Jacobs et al., 1995; Masur, Sliwinski, Lipton, Blau, & Crystal, 1994) may predict dementia incidence. In addition, Masur et al. (1994) found the digit symbol subtest from the Wechsler adult intelligence scale-revised (WAIS-R; Wechsler, 1981) to be predictive of dementia incidence, whereas Jacobs et al. found another WAIS-R subtest, word similarities, to be significantly related to incidence of AD.

Although these indices of verbal ability (category fluency, Boston naming), speeded psychomotor skill (digit symbol), and abstract reasoning (word similarities) have been found to be predictive of dementia incidence, the most salient predictor of who will become afflicted with dementia is baseline episodic memory performance. Numerous studies have found that individuals who perform poorly on measures of recall and recognition are more likely to develop dementia after a follow-up interval than their superior-performing counterparts. For example, Masur and colleagues (Masur, Fuld, Blau, Crystal, & Aronson, 1990; Masur et al., 1994) have found the delayed recall measure from the Buschke selective reminding test to be an effective predictor of dementia incidence. Similar relationships have been reported with the Fuld object memory test (Fuld, Masur, Blau, Crystal, & Aronson, 1990; Masur et al., 1994), and the logical memory subtest of the Wechsler memory scale (Linn, et al., 1995).

Tierney et al. (1996) addressed the relative importance of different memory tasks in predicting incident cases of AD. They examined 123 memory-impaired patients and identified 29 probable AD patients after a two-year follow-up period. At baseline, all subjects completed a comprehensive neuropsychological battery including multiple indices of memory, verbal fluency, and psychomotor speed. The results of a logistic regression analysis, predicting AD status (yes/no), indicated that two tests (delayed recall from the Rey auditory verbal learning test and the mental control subtest of the WMS) were predictive of dementia incidence. Furthermore, these variables were fairly successful at correctly classifying the proportion of patients diagnosed with dementia (sensitivity 76%), as well as correctly identifying those who were free of dementia (specificity 94%). This resulted in an overall accuracy rate of the model of 89%. The additional measures of verbal fluency and psychomotor speed added little diagnostic accuracy in predicting which individuals would develop AD. Taken together, the results from this research indicate that episodic memory measures may be the most salient predictors of dementia incidence.

Although the relationship between episodic memory performance and dementia incidence is well established, it is also apparent that not all memory tasks are created equal. For example, tasks may differ in terms of the amount of cognitive support that is offered the individual (see Bäckman, Mäntylä, & Herlitz, 1990; Herlitz, Lipinska, & Bäckman, 1992, for reviews). Cognitive support refers to characteristics of memory tasks that make successful retrieval more or less likely. For example, free recall of unrelated words can be considered to be a task with relatively little cognitive support. This is due to the fact that the to-be-remembered items have little inherent organizability, and the recall condition offers no cues as to which items should be remembered. One can increase the level of cognitive support in this task by selecting words from several superordinate categories (e.g., articles of clothing, musical instruments). This change makes the task more supportive by supplying organizational structure to the materials. In this manner, the subject can arrange the words into their respective categories facilitating memory for these items (Bäckman & Wahlin, 1995). Cognitive support can also be manipulated at retrieval. Instead of the relatively impoverished retrieval conditions prevailing in free recall, a cued recall task may be given whereby the subject is prompted by word stems or category names in order to improve recall performance. In addition, a recognition task, in which subjects are asked to choose among target and distractor items, could be used to further increase the supportive nature of the retrieval task (Craik, 1983).

Several authors have suggested that the supportive nature of episodic memory tasks can influence the success of these tasks in detecting early cases of dementia. For example, Branconnier, Cole, Spera, and DeVitt (1982) found that tasks that are well supported (e.g., recognition) were the best discriminators between mild cases of dementia and normal aging. A possible reason for this finding is that many older adults, especially very old adults, may have deficits in cognitively demanding tasks such as free recall, whereas recognition and cued recall are relatively well preserved (Bäckman & Larsson, 1992; Craik & McDowd, 1987; Schonfield & Robertson, 1966). Thus, when deficits in the well-supported task are present, this may indicate conditions other than normal aging (e.g., dementia, depression).

The role of cognitive support in episodic memory tasks in predicting incidence of dementia has received less empirical attention. Although several studies have included multiple measures of episodic memory (e.g., Fuld et al., 1990; Masur et al., 1990), the lack of systematic variation among memory tasks has made firm conclusions regarding the relationship between cognitive support and dementia status difficult. Small, Herlitz, Fratiglioni, Almkvist, and Bäckman (1997) attempted to examine the issue of cognitive support in episodic memory and incidence of dementia by including multiple episodic memory tasks that varied in terms of a number of encoding and retrieval demands. Specifically, tasks were chosen that varied in terms of encoding demands (e.g., unrelated vs. organizable items), retrieval conditions (e.g., recall vs. recognition), as well as the nature of the materials that were examined (e.g., faces vs. words). In this study, 26 incident cases of AD were identified after a three-year follow-up interval, whereas 179 remained nondemented. In addition to the memory tasks, measures of visuospatial ability (block design, clock test, Poppelreuter's figures), verbal fluency (letter and category fluency), and primary memory (digit span) were included to examine the predictive relationship between these measures and incidence of AD.

Results from a logistic regression analysis indicated that three measures, recall of organizable words, face recognition, and letter fluency, were significant predictors of AD. Other less supported memory tasks (e.g., free recall of unrelated words), as well as other measures of visuospatial ability, category fluency, and primary memory were not predictive of dementia incidence. By examining the sensitivity and specificity of the model, it was determined that the two memory measures, organized word recall and face recognition, provided the greatest ability to detect who would become afflicted with AD (sensitivity 62%). On the other hand, although letter fluency added significantly to the logistic regression equation, its role was in improving the ability of the model to detect individuals who would remain nondemented (specificity 99%). Thus, among the predictors of dementia incidence, it was the two episodic memory tasks that were most effective at predicting incident cases of AD. In addition, the results of this study confirmed the hypothesis that more supported memory tasks (i.e., face recognition, recall of organizable words) rather than less supported tasks (e.g., recall of unrelated words) are most effective at predicting incident cases of AD.

In summary, the results from studies that have examined preclinical cognitive markers of dementia provide important information as to the changes that accompany the pathogenesis of AD. Specifically, tests of episodic memory performance appear to be the most powerful predictors of dementia incidence. On the one hand, recent research suggests that episodic memory tasks that are cognitively well supported are the best predictors of development of dementia. On the other hand, the results from all relevant studies have shown that markers of other abilities, including verbal and visuospatial skill, are less effective predictors of dementia incidence. Thus, it seems wise to include episodic memory tasks, and especially those that are well supported (e.g., recognition, recall of organizable words) when developing a predictive model for AD.

7.10.4 DETECTION OF DEMENTIA

In the previous section, we described the effectiveness of cognitive performance measures, especially those that index episodic memory functioning, in predicting who will become demented. In this section, we change our focus slightly in that it is not the development of dementia that we are interested in; rather, the issue of interest is the ability to differentiate between adults who are already mildly demented compared with nondemented adults. For the purpose of the present chapter, we are interested in whether those same measures of cognitive performance that are able to predict development of dementia would be effective at discriminating between nondemented adults and persons who are in an early phase of the disease.

Two main statistical methods have been used to differentiate normal old from AD individuals, namely the algorithm approach (e.g., Fuld, 1984) and the discriminant analysis approach (e.g., Storandt, Botwinick, Danziger, Berg, & Hughes, 1984). In the following, we will limit our review to the more commonly used discriminant analysis method. In this method, researchers have tried to determine the cognitive tasks or tests that best discriminate between normal old and mild AD patients. As is true with research attempting to delineate preclinical markers of AD, the uncertainties regarding dementia diagnoses are problematic for attempts to detect dementia. Thus, it may be that the differentiation between normal old adults and AD patients is based on a less than perfect "answer key," which also means that we do not get a fair evaluation of the discriminative power of the cognitive tests.

With this problem fresh in mind, we now turn to the results from studies investigating how well cognitive measures can discriminate between normal old adults and early AD patients. Most studies have found that tasks assessing episodic memory are particularly sensitive in detecting early dementia (e.g., Almkvist & Bäckman, 1993a; Herlitz et al., 1995; Storandt et al., 1984; Welsh, Butters, Hughes, Mohs, & Heyman, 1991, 1992). For example, in groups of AD patients and community volunteers, matched on age and education, Welsh et al. (1991) found that a measure of episodic memory, delayed word recall, correctly classified 96% of the control subjects and 86% of the patients. However, the authors of this study pointed out that the AD patients were compared with high-functioning control subjects, and that the results cannot be generalized to older adults in the community at large.

A study investigated the relative importance of episodic memory tasks and visuospatial tasks in the detection of dementia (Herlitz et al., 1995). Subjects were sampled from the general population in Stockholm, Sweden. Thus, all subjects were randomly sampled from the same population, and were generally older than subjects in other studies. In addition to standardized neuropsychological tests, the test battery included specialized measures derived from the experimental literature to examine various features of episodic memory. Three-hundred and ninety-eight normal older adults and 63 mildly demented individuals participated in this study. The group of mildly demented adults consisted of patients diagnosed with AD, VaD, mixed dementia (AD and VaD), Parkinson's disease, and alcohol dementia. Separate analysis was conducted for the AD group and the entire dementia group, but it was found that the results were similar irrespective of dementia etiology.

The results of this study demonstrated that it is possible to differentiate those with mild dementia from normal old adults using mainly measures of episodic memory. Of the five measures that contributed to the differentiation of dementia from normal aging, four were indicators of episodic memory and, specifically, measures of recognition and cued recall. Thus, in contrast to the Welsh et al. (1992) study, no free recall task was included in the function, but rather highly supportive measures of episodic memory. As with the research on dementia incidence, it was hypothesized that a possible reason for this result is that many nondemented older adults, especially those in advanced age, already have deficits in free recall (see Craik & Jennings, 1992, for a review), whereas recognition and cued recall may be relatively well preserved. In the Welsh et al. study (1992), subjects were recruited from a clinical population with healthy volunteers from the community. Thus, differences in cognitive ability between the nondemented subjects in Welsh et al. (1992) and those in Herlitz et al. (1995) may have contributed to the differences in results.

Although episodic memory tasks provide a good classification of normal old and mildly demented subjects, a number of subjects are misclassified by these measures. Correct classification rates, ranging from 92%–96% and 67%–89%, have been achieved for normal old and mildly demented subjects, respectively (Almkvist & Bäckman, 1993a; Herlitz et al., 1995; Welsh et al., 1991, 1992). Herlitz et al. (1995) found an overall classification rate of 90.7%, misclassifying 22 normal controls as demented and 21 demented subjects as normals. Further analysis showed that the misclassified normal controls were older and had lower MMSE scores than the correctly classified normal older adults. By contast, the group of mildly demented subjects that were misclassified as normal controls, were younger, had higher MMSE scores, and consisted of more males than the group of correctly classified mildly demented subjects.

In a later study, Herlitz, Small, Fratiglioni, Almkvist, and Bäckman (1997) were able to provide follow-up information regarding dementia incidence of the subjects that were incorrectly classified as demented, by reassessing all subjects three years after the initial examination. It was found that out of the 14 surviving subjects (eight subjects died from time 1 to time 2), 10 had developed AD. This suggests that the misclassification of normal old as demented, by the cognitive tests administered at time 1, was fairly accurate in selecting subjects who would eventually develop dementia. Hence, the majority of the misclassified subjects may not have been misclassified at the baseline assessment, but rather been in an early phase of dementia already at time 1.

The reasons for the classification of subjects, who had a clinical diagnosis of dementia at time 1 as nondemented, were different. At time 2, it was found, among the 15 surviving subjects, that two subjects had their diagnosis changed from demented to nondemented. Thus, these subjects had received, incorrectly, a clinical dementia diagnosis at time 1 that was later corrected. However, the majority of subjects in this group, of course, remained demented, and it is reasonable to assume that the cognitive tests were unable to discriminate between the group of correctly classified dementia patients and this group of subjects who, were younger, had a higher MMSE scores, and consisted of more males. Thus, it appears that the clinical diagnosis of dementia is easier in younger, male, and highly educated subjects than it is in older, female, and less educated persons. These results indicate that cognitive tests, and especially tests of episodic memory, are effective at detecting subjects in a very early stage of dementia who are easily missed in the clinical diagnosis due to confounding variables such as age, education, and gender. Yet, although cognitive tests may be useful in the preclinical detection of dementia, these tests may also miss a sizeable proportion of prevalent dementia cases due to insensitivity to the same demographic indices.

Taken together, the results on cognitive detection of dementia show that episodic memory measures are particularly effective at discriminating between normal old adults and AD patients. In addition, this line of research demonstrates that memory tasks may be effective in the detection of AD at a very early phase—a finding which is consistent with research conducted on the incidence of AD (e.g., Small et al., 1997; Tierney et al., 1996). In particular, results indicate that performance on highly supported tests of episodic memory performance are especially salient predictors of future cases of dementia, as well as good discriminators between normal elderly adults and those in mild stages of the disease process.

7.10.5 STAGING OF DEMENTIA

It is of considerable interest whether the same or different cognitive tasks are particularly useful in the detection and staging of AD, respectively. Similarities or differences with respect to this issue are relevant to the understanding of the progression of AD. On the one hand, if the same cognitive functions would be involved in both detection and staging of dementia, this would mean that decline in these functions would be linear across the pathogenesis and, ultimately, that some cognitive abilities are relatively well preserved throughout the disease. On the other hand, if different functions are involved in the detection and staging of dementia, it would imply that different cognitive abilities may decline at different times in the disease process and at different rates.

In studies investigating staging of AD, the most common method has been to use a global cognitive assessment instrument (e.g., the MMSE) as the criterion variable. There are, of course, problems related to this method, the most important being that the global assessment instrument used consists of a given set of cognitive tasks, which means that how well a certain set of cognitive test measures can stage dementia, by means of discriminant analysis, is dependent on how well they are correlated with the criterion measure. Only a few studies have investigated the ability of cognitive tests to stage dementia, that is, to separate mildly demented subjects from moderately demented subjects (Almkvist & Bäckman, 1993a; Herlitz et al., 1995; Hill, Storandt, & LaBarge, 1992; Welsh et al., 1992). These studies have found that, although episodic memory tasks are critical in detecting dementia, tasks drawing on verbal skills and visuospatial abilities are more effective at staging dementia. For example, Hill et al. (1992) used the clinical dementia rating scale (George et al., 1990) as the criterion variable, and found that tasks assessing verbal naming, visuospatial copying, and episodic recognition separated between mildly and moderately demented AD patients, with an overall correct classification rate of 86.2%. Almkvist and Bäckman (1993a) staged very mildly, mildly, and moderately demented patients, with the MMSE as the criterion variable. This study found that tasks assessing visuospatial ability, semantic memory, psychomotor speed, and episodic memory separated the three groups of patients with an overall correct classification rate of 64%.

Herlitz et al. (1995) also used the MMSE as the criterion variable and found an overall classification rate of 84.3% in the differentiation of mildly and moderately demented subjects. As in the corresponding analysis on detection of dementia, all analyses were done with the patient group consisting of either AD patients or a mixture of dementia subjects. However, such a division made little difference to the outcome. Four test measures were included in the discriminant function, a free recall task, backward digit span, block design (WAIS-R; Wechsler, 1981), and modified trail making A (Armitage, 1946). Thus, in contrast to the tasks involved in the detection of dementia, two of the tasks in the discriminant function were visuospatial in nature and one was a measure of primary memory. Only one of the tasks in the discriminant function was an episodic memory measure. These results suggest that visuospatial and primary memory abilities may deteriorate later and/or at a slower rate than episodic memory functions in the early stages of dementia (see also Almkvist & Bäckman, 1993b).

The results on staging of dementia are less consistent than are the studies on detection, probably because different criterion variables have been used across studies. In addition, comparatively little research has addressed the efficacy of cognitive measures in the staging of dementia, hence making firm conclusions difficult. However, the majority of studies addressing this issue indicate that episodic memory plays a less dominant role than other cognitive abilities in the differentiation between mildly and moderately demented patients. We contend that the most parsimonious interpretation of these results is that cognitive abilities such as visuospatial functioning, semantic memory, and primary memory deteriorate later and/or at a slower rate than episodic memory in the early stages of dementia.

7.10.6 PROGRESSION OF DEMENTIA

In addition to studies that have examined the cognitive performance of mildly to moderately demented adults through attempts to stage dementia severity, research has focused on longitudinal changes in cognitive performance in these patients. Ultimately, information regarding rates of change, and whether there is a differential nature of cognitive change at later stages of dementia severity can only be inferred from studies that have examined data from more than one time of measurement. Studies that have attempted to stage and detect dementia are hampered by the lack of longitudinal evidence when deriving cognitive profiles of disease progression. The studies that we review in this section are based on data from more than one measurement point.

Grady et al. (1988) examined changes in memory, attentional, verbal, and visuospatial functioning in a group of 11 AD patients. They noted that among all of the measures of cognitive performance, impaired episodic memory performance was the first sign of cognitive dysfunction in dementia. Further, these investigators reported that visuospatial functioning and verbal ability were among the last abilities to show deficits in their sample of AD patients. Similar results were reported by Almkvist and Bäckman (1993b). In this case, longitudinal changes in a range of cognitive functions in AD were examined over a two-year period. Almkvist and Bäckman found that episodic memory measures exhibited the least amount of decline over the retest interval, but when the estimated onset of decline was examined, these measures were the first to exhibit decline in AD. Moreover, visuospatial functioning, indexed by block design and object assembly from the WAIS-R, exhibited a moderate rate of decline over the retest interval but were among the last measures to decline in the sample of AD patients.

Additional evidence for verbal and visuospatial functioning declining at a later point in the disease process comes from a study by

Haxby et al. (1990). This study examined changes in cognitive functioning over a two-year follow-up period in a group of 11 mildly demented AD patients. Haxby and colleagues found that the impairment that dominated at the initial time of measurement were localized to tasks measuring memory and ability to sustain attention. However, "neuropsychological impairment in mildly impaired AD patients became more severe and widespread as the disease progressed" (Haxby et al., 1990, p. 757).

Small and Bäckman (1997) also examined longitudinal changes in episodic memory, visuospatial functioning, and verbal fluency in a group of 26 AD and 10 VaD patients. In this study, longitudinal changes were less pronounced in the episodic memory measures, whereas performance in the visuospatial and verbal domains exhibited dramatic negative changes. Further, the changes in performance varied minimally as a function of dementia type, indicating approximately equivalent declines in performance for both the AD and VaD patients.

Taken together, the results from longitudinal studies that have examined changes in cognitive performance of mildly demented persons suggest a differential pattern of change depending on what domain of cognitive functioning is being measured. Specifically, changes in episodic memory functioning of mildly demented adults are less pronounced, probably as a result of the bulk of the dementia-related declines having occurred already. Certainly, this hypothesis is supported by the fact that impairment of episodic memory may be seen in persons who will later develop dementia several years before a clinical diagnosis is possible (e.g., Jacobs et al., 1995; Linn et al., 1995; Tierney et al., 1996). On the other hand, visuospatial and verbal functioning exhibit stronger declines at later stages of the progression of the disease. The results from the longitudinal studies thus converge with those seen in cross-sectional research attempting to stage dementia severity through cognitive performance indices. In particular, measures of visuospatial and verbal abilities may be particularly effective in staging dementia, because these abilities tend to decline at a later stage of the dementing illness than episodic memory skills.

7.10.7 TRAJECTORY OF DECLINE

Although there is some evidence to suggest that not all cognitive abilities decline at the same time, there is additional evidence to suggest that the shape of the decline function may also vary as a function of dementia severity. Several authors have suggested that the cognitive changes accompanying dementia follow a nonlinear pattern. For example, Haxby et al. (1990) examined the cognitive performance of 16 AD patients. They noted that changes in the WAIS, MDRS, and MMSE followed a biphasic pattern of change, that is, there was an initial plateau of performance followed by a sharp linear decline in cognitive functioning.

Additional evidence for nonlinear changes in cognitive performance in dementia comes from research reported by Brooks and his colleagues (Brooks et al., 1993; Brooks & Yesavage, 1995). These investigators proposed a trilinear model of cognitive change in AD, in which the cognitive decline function in AD is conceptualized as a tripartite curve. According to this view, there is an initial period of stability before detectable decline, followed by a period of decline, and ending with a final period of relative stability. Longitudinal evidence from Helmes et al. (1995) demonstrates that performance on their scale of global cognitive functioning, the extended scale for dementia, follows a trilinear pattern of change in dementia patients much like Brooks et al. have postulated.

The possibility of a nonlinear pattern of cognitive change in dementia has several implications for the way in which we study progression of cognitive changes across the disease process. For example, the use of statistical methodologies that assume linear changes in performance (e.g., multiple regression, analysis of variance) may be inappropriate because of the nonlinear changes that are embedded in performance. Perhaps the greatest implication deals with the number of measurement occasions that we choose to follow our longitudinal samples for. Obviously, in order to describe nonlinear patterns of change, at least three measurement occasions are required. Brooks et al. (1993) suggested that in order to adequately describe the trilinear decline function in AD, five measurement occasions should be planned for. In addition, if we wish to examine the trilinear shape of changes in memory and other cognitive abilities, even more measurement points will need to be examined. Recall from our reviews of incidence, detection, staging, and longitudinal changes, that episodic memory functioning may be the first cognitive ability to decline in dementia, whereas other cognitive functions, such as verbal and visuospatial skill, appear to decline at a later stage. The differential onset of changes in individual cognitive measures implies that persons will be at different stages in the trilinear model depending on what domain of functioning is being indexed. For example, some individuals may be experiencing decline in episodic memory functioning, but be at the initial plateau stage of verbal ability because they are relatively early in the course of dementia. By contrast, other persons may be experiencing decline in verbal ability, but be at the later plateau stage in terms of episodic memory functioning. Furthermore, this argument assumes that performance in each domain of functioning follows a similar trilinear pattern of decline, with comparable duration in each part of the function. Because much of the work on non-linear change in dementia has focused on more global indices of cognitive functioning (e.g., Brooks et al., 1993; Helmes et al., 1995), rather than individual domains of performance, it is unclear whether every domain of cognitive function (e.g., verbal ability, visuospatial functioning) will follow a similar trajectory of decline. Clearly, although the results presented here are suggestive of nonlinear changes in the cognitive performance of demented adults, additional evidence is necessary before firm conclusions can be made regarding the onset, shape, and duration of the respective change functions.

7.10.8 PREDICTORS OF DEMENTIA-RELATED DIFFERENCES AND CHANGES

We have argued that the changes accompanying dementia are somewhat predictable. For example, on the one hand, we have marshalled evidence to indicate that declines in episodic memory performance are among the first signs of a dementing illness. Indices of verbal and visuospatial functioning, on the other hand, begin to deteriorate markedly only after the diagnosis of dementia has been made and proceed to decline with increasing severity of dementia. In this section, we look again at the ability to predict dementia-related differences and changes in cognitive performance. However, although our previous attempts to examine the cognitive transitions in dementia have focused on the temporal progression of the disease, we focus here on whether cognitive performance is predictable by different demographic, biological, and psychometric indices.

In research on normal aging, there is a great tradition of using individual-difference variables to predict age-related differences, and age-related changes, in cognitive functioning (see Hultsch & Dixon, 1990; Salthouse, 1991, for reviews). For example, a number of studies have found age-related differences being predicted by demographic characteristics such as age, gender, and education (e.g., Herlitz, Nilsson, & Bäckman, in press; Inouye, Albert, Mohs, Sun, & Berkman, 1993; Wiederholt et al., 1993). Similarly, other studies have focused on the ability of biological indices, such as general health or vitamin status, in predicting cognitive performance (e.g., Hultsch, Hammer, & Small, 1993; Wahlin, Hill, Winblad, & Bäckman, 1996). Finally, investigators have identified a number of basic information processing indices, including measures of processing speed (e.g., Salthouse, 1991) and working memory (e.g., Hultsch, Hertzog, & Dixon, 1990; Salthouse, 1991) as important predictors of cognitive performance among normal elderly adults.

Although the role of these types of individual-difference variables in predicting age-related differences and changes in performance is well documented in the normal aging literature, it is less clear whether these same classes of variables can predict dementia-related differences or dementia-related changes in cognitive performance. Using global performance indices as target variables, a number of factors have been found to be associated with a more rapid rate of progression, including early onset age (e.g., Burns, Jacoby, & Levy, 1991), language deficits (e.g., Boller, Becker, Holland, & Forbes, 1991), visuospatial deficits (e.g., Becker, Huff, Nebes, Holland, & Boller, 1988), and psychomotor slowing (e.g., Berg et al., 1984). However, other studies have found the relationship between these individual-difference predictors and cognitive progression to be equivocal (e.g., Almkvist & Bäckman, 1993b; Mortimer, Ebbit, Jun, & Finch, 1992).

Bäckman, Hill, Herlitz, Fratiglioni, and Winblad (1994) reported that the role of individual-difference variables in predicting performance on episodic memory tasks is substantially reduced in dementia. In this study, Bäckman et al.(1994) examined the relationship between a variety of subject-related variables corresponding to the demographic (e.g., age, education, onset age, activities of daily living), biological (ferritin, albumin, folic acid, fructoseamine/albumin, vitamin B12, and thyroid stimulating hormone), and psychometric (e.g., block design, digit span) domains and performance on two episodic memory factors, recall and recognition. They found that after controlling for differences in disease severity, only two predictors contributed to performance. In one case, a marker of fluid intelligence (block design) was positively related to performance on a factor of word recall, and in the other, age was negatively related to performance on a measure of word recognition. However, the relative paucity of individual-difference variables that could predict dementia-related differences in episodic memory functioning stands in contrast to the variety of such measures that were significant predictors of episodic memory performance in the sample that contained nondemented adults from the same study population (e.g., Bäckman & Wahlin, 1995; Hill, Wahlin, Winblad, & Backman, 1995; Wahlin et al., 1993). In a related study, Hill, Bäckman, Wahlin, and Winblad (1995) demonstrated evidence for a limited number of predictors being related to visuospatial performance in dementia, once severity of dementia was statistically controlled. Specifically, using Poppelreuter's figures, the clock test, and block design as criterion variables, only one relationship out of a total of 15 possible predictor variables was observed, namely that education was positively related to block design.

Using the study of Bäckman et al. (1994) as a guide, we recently investigated whether the relatively paucity of individual-difference predictors also held when changes in the cognitive performance of demented adults were examined (Small & Bäckman, 1997). In this study, using the same constellation of predictor variables, we sought to determine whether longitudinal changes in episodic memory, visuospatial functioning, and verbal fluency could be predicted by these indices. Results indicated that none of the demographic, biological, or psychometric indices of performance were significant predictors of change in any domain of cognitive functioning. We concluded that although the rate of cognitive deterioration in dementia is highly variable, this variability in change appears to generalize across a variety of demographic, psychometric, and biological characteristics. A possible reason for the lack of effects is that the role of individual-difference variables in cognitive functioning in dementia is overshadowed by the pathogenetic process itself. Specifically, much of the systematic variation in performance may be absorbed by the severity of the disease (as indexed by, for example, the MMSE), hence leaving little predictive power to other subject-related factors.

In summary, it appears that although the role of individual-difference variables in predicting cognitive performance of nondemented adults has a long and successful heritage, the importance of these same variables appears to be substantially reduced in dementia when contrasted against the severity of the disease itself.

7.10.9 CONCLUSIONS AND EXTENSIONS

In this chapter, we have seen that as individuals make the transition from normal aging to dementia, as well as the transition from milder to more severe stages of dementia, there is a relatively predictable pattern of cognitive changes. The results from studies that have examined incident cases of dementia (e.g., Small et al., 1997; Tierney et al., 1996) indicate that baseline measures of episodic memory performance are the best predictors of who will become demented. Similarly, results from studies that have attempted to discriminate between nondemented and mildly demented adults on the basis of cognitive performance measures suggest that episodic memory performance is an important factor in making these discriminations (e.g., Herlitz et al., 1995; Welsh et al., 1992). However, the predictive role of verbal ability, visuospatial functioning, and primary memory at these early stages of dementia is considerably smaller. It is only after the disease has progressed that visuospatial functioning, verbal ability, and primary memory begin to deteriorate markedly. This is evidenced in studies that have found these measures to be effective at staging disease progression (Herlitz et al., 1995; Hill et al., 1992; Welsh et al., 1992), as well as in studies that have assessed longitudinal changes directly (Almkvist & Bäckman, 1993b; Grady et al., 1988; Small & Bäckman, 1996).

Although we still lack a complete understanding of why the different domains of cognitive functioning follow such a pattern of deterioration, analyzing the trajectory of cognitive decline in light of the biological changes that accompany AD may provide useful information. Specifically, it may be argued that the differential change in cognitive functioning is consistent with models of the pathogenetic process in AD based on both neuropathological (Arrigada, Growdon, Hedley-White, & Hyman, 1992, Braak & Braak, 1991, 1995) and brain-imaging (Grady et al., 1988, 1990) data. For example, Braak and Braak contend that initial changes in the brain structures of AD patients occur in the medial temporal regions (e.g., the entorhinal cortex and the hippocampus) and, as the disease process advances, these changes radiate into neocortical structures. It is well known from research with amnesic patients that the hippocampal formation plays an important role in episodic remembering (e.g., Mayes, 1988; Squire, 1987). Recent brain activation research using positron emission tomography supports the view that episodic memory is heavily dependent on the integrity of the medial–temporal cortex (e.g., Grady et al., 1995; Nyberg, McIntosh, Houle, Nilaaon, & Tulving, 1996). It is also known that the neocortical association areas are particularly critical to performance across a variety of verbal and visuospatial tasks (e.g., Raichle et al., 1994; Ungerleider & Haxby, 1994). Thus, the pattern of dementia-related cognitive decline across the pathogenesis makes perfect sense in view of independent research addressing the biological basis of human cognition. From a somewhat different perspective, it may further be noted that episodic memory performance has been found to be an especially sensitive cognitive indicator of a variety of conditions, including herpes simplex encephalitis (Williams, Watts, Macleod, & Matthews, 1988), hypoxic damage (Hashtroudi, Parker, DeLisi, & Wyatt, 1983), toxic changes (Teitelbaum et al., 1990), depression (Bäckman & Forsell, 1994), alcohol intoxication (Nilsson, Bäckman, & Karlsson, 1989), and sleep deprivation (Polzella, 1975). Tulving (1993; see also Schacter & Moscovitch, 1984) has speculated that episodic memory evolved relatively late phylogenetically and develops relatively late ontogenetically relative to other forms of memory and cognitive functions. Thus, following Ribot's law (Ribot, 1882), it may perhaps be expected that episodic memory should be especially prone to brain insufficiencies such as dementia.

7.10.10 SUMMARY

In summary, although the evidence we have presented here was gathered from a variety of sources that often differed in terms of sample composition, dementia severity, and selection of the specific cognitive tests that were employed, a relatively predictable pattern of cognitive deterioration in dementia was identified. On the one hand, it appears that episodic memory is the first ability to deteriorate at or even before the dementia diagnosis is rendered. On the other hand, visuospatial and verbal functioning decline somewhat later in the disease process, and this is likely to reflect the fact that additional brain structures are being affected by the disease process. We hope that this chapter, with its insights into the pattern of cognitive deterioration in dementia, may generate some considerations in the clinical setting. For example, knowledge pertaining to which specific cognitive tasks that may be particularly sensitive in detecting very early dementia-related changes (e.g., highly supported episodic memory tasks) should be helpful in improving the accuracy of early clinical diagnoses. Although we currently lack effective pharmacological or behavioral intervention procedures for AD and related dementia disorders, such procedures may be developed in the years to come. If that were to be the case, it is conceivable that treatment efficacy would be greatest at the earliest possible phase in the disease process. In addition, even in the present situation, accurate diagnostic information early in the disease process may be useful for the patient, practitioners, and caregivers alike in order to adjust optimally to the impending disease process.

7.11.1 INTRODUCTION

The research and clinical treatment of suicidal persons among any age group presents enormous challenges. One aspect of those challenges is to consider the influence of how societies view and tolerate suicidal behavior among their members. Stillion and McDowell (1996) have provided an historical overview of how suicide has been viewed in the Western world. Views on suicidal acts have ranged from Socrates' description of "honorable exits" in 399 BC to the Council of Toledo's declaration that instituted excommunication for the deceased suicide victim or attempter in AD 693. The recent US public health perspective (*Healthy People 2000,* 1991), which began in the 1960s (Shneidman, Farberow, & Litman, 1961), views suicide as an outcome of intolerable psychological distress and inadequately treated mental disorders. This more recent perspective, however, is not unanimously held in the USA. The Hemlock Society (Humphry, 1991, 1992) and a recent ruling by the 9th US District Circuit Court of Appeals (Compassion in Dying vs. State of Washington, 1996) consider suicide a right of individuals. Moreover, many persons hold the view that some persons have more of a right to this act than others; suicide in youth is still considered a tragedy relative to suicides by older, disabled, and less healthy persons (Marks, 1988–1989).

This perception, along with the higher percentage of media coverage devoted to suicides among young and middle-aged persons relative to the elderly could be interpreted as higher rates among youthful groups. However, in 1993 the suicide rate in the USA for persons age 85 and older was twice the rate than persons age 15–19 (10.9 per 100 000 compared to 22.8 per 100 000). If we consider the rates for white males, the highest risk group in the USA, the ratio is more than tripled: adolescents age 15–19 have a rate of 18.5 per 100 000, and older adults age 85+ have a rate of 73.6 per 100 000. This latter rate is over six times the rate of all age-adjusted suicides (National Center for Health Statistics, 1996).

In addition to agist views that consider an older life less valued than a young life, psychological research and clinical interest in elderly suicide may have been limited due to the fact that psychologists (as well as other mental health professionals) rarely see older patients who are suicidal. Generally speaking, older persons with mental disorders rarely seek help from mental health professionals, preferring to visit their primary care physician instead (German, Shapiro, & Skinner, 1985). In addition, psychologists may be less likely to see suicidal patients than psychiatrists: psychologists have a one-in-five chance, and psychiatrists a one-in-two chance of losing a patient to suicide during their careers (Chemtob, Hamada, Bauer, Kinney, & Torigoe, 1988; Chemtob, Hamada, Bauer, Torigoe, & Kinney, 1988). However, as depression is better recognized and effective treatments for depression are increasingly applied to the elderly population (NIH Consensus Development Panel, 1992), as more older persons receive mental health treatment, and as more psychologists become specialists in treating elderly patients (Niederehe, Cooley, & Teri, 1995), the probability that psychologists will encounter suicidal older adults will inevitably increase.

It is hoped that this review will highlight the incompleteness of our current understanding of late life suicide, and make apparent the need for more psychological research on this tragedy. In particular, the epidemiology and putative "risk factors" for completed suicides, and suicide completers' interface with the health system, are surveyed. Also reviewed are studies on elderly attempters, and research on the bioethical issues involved in assisted suicides. Suggestions for further research, including the consideration of possible subgroups at risk, and recommended clinical resources, are also discussed.

7.11.2 SOURCES OF DATA FOR STUDIES OF SUICIDAL BEHAVIOR IN THE ELDERLY

7.11.2.1 Mortality Data

The US national data on gender, age, race, marital status, and method of death characteristics of completed suicides are based on vital statistics information gathered by the Center for Disease Control and Prevention's National Center for Health Statistics. The source of this information is derived from death certificates that come from each state, each state being responsible for its own vital registry system. In addition to the variation by state policies, the qualifications for the coroner, medical examiner, or others responsible for completing death certificates also varies widely. The person may be an elected or appointed layman, lawyer, sheriff, mortician, general practitioner, or forensic pathologist. It is generally agreed that what systematic error exists, it will be toward conservative estimates: there are more "missed" suicide deaths than deaths of other causes miscounted as suicides (see O'Carroll, 1989 for a review). Clark (1992) has suggested that these undercounts are probably around 5%. Despite these sources of variation, mortality data has been used in epidemiologic methods to measure the magnitude of suicide as a public health problem, and assess the effects of public health policies (Healthy People 2000, 1991).

7.11.2.2 Community Studies Using the Psychological Autopsy Method

Although determining the cause of death in suspected suicides usually requires forensic work, such as in-depth interviews with the victims' associates, these efforts are not routinely recorded and available for research use. Therefore, although information such as recent life events, history of hospitalizations, or mental state of the person prior to the suicide may have been assessed, it is not systematically recorded at a state or national level. The psychological autopsy (PA) method was developed to integrate such information in order to achieve a better understanding of the psychological circumstances contributing to a death, and has been applied to a number of communities and populations. Clark and Horton-Deutsch (1992) describe the evolution of this method since the 1930s. As used today, the PA constructs a detailed picture of the victim's psychological state prior to death, including psychiatric symptomatology, behavior, and life circumstances in the weeks or months before death. The gathering of this information includes interviewing knowledgeable informants, reviewing available clinical records, and comprehensive case formulation by one or more mental health professional with expertise in postmortem studies (Beskow, Runeson & Asgard, 1990; Clark & Horton-Deutch, 1992). Clark and Horton-Deutch outline 12 standards for using this method in suicide research.

The application of the PA to suicides among the elderly has been slow in coming, due to the belief that older suicide victims are socially isolated from both formal and informal contacts and therefore there would be few knowledgeable informants to obtain data from. To the contrary, Younger, Clark, Oehmig-Lindroth, and Stein, (1990) described ample numbers of informants available: In Cook County, Illinois, 70% of elderly suicides were married; 90% had one knowledgeable informant and 50% had two informants. Several studies have further demonstrated that the PA method can be applied to elderly suicides: Conwell and Brent (1995) have reviewed a number of PA studies that compare younger and older adults. It is important to note that few psychological autopsy studies in general, and none that are focused on elderly suicides, have yet included appropriate case-controls that would maximize the benefits of this methodology.

7.11.2.3 Clinical Follow-up Studies

As will be discussed below, the majority of suicide victims have some sort of mental disorder. Among the elderly, first episode, unipolar depression is the predominating disorder among completed suicides (Conwell, 1994). A relatively efficient approach to obtaining data on suicides is to follow-up persons most at risk; those with depressive disorders. This has been most frequently conducted through retrospective cohort studies. In addition to the challenge of tracking of persons after treatment, this method also relies on medical records that are notoriously variable in accuracy and completeness. Although this approach has been used to examine suicides among young adult and middle-aged persons, few studies have examined what characteristics, in addition to clinical treatment for depression, place the elderly at risk for suicide. Of the studies that have considered "elderly" persons (those 50 and older), some have suggested that delusional depression is a risk factor, where other have not found this type of depression to be related to increased risk for later suicide (Coryell & Tsuang, 1982; Robinson & Spiker, 1985; Roose, Glassman, Walsh, Woodring, & Vital-Herre, 1983). When specific age groups such as the elderly are examined in these retrospective studies, limited sample sizes and variable follow-up periods often limit both the power to reliably discern risk rates and generalizability to other clinic populations.

Since the elderly are less likely to seek or obtain mental health services:(German et al., 1985), the biases in this approach are likely to favor the documentation of those more likely to see mental health services: women (Kessler, Brown & Broman, 1981; Nathanson, 1977), those with more severe depression, comorbid personality disorder, and persons who have used an overdose method (Lindesay, 1986; Vieta, Nieto, Gastó, & Cirera, 1992). Although it is important to study these biased samples in order to understand what are safe and effective treatments in such service contexts, they minimally overlap with community samples described by epidemiologic and PA methods: Characteristics of the later life suicides in epidemiologic populations and community samples include men, those with late onset, unipolar depression, persons unlikely to have received mental health care, and those who have used a firearm as a suicide method.

7.11.2.4 Suicide Attempter Studies

The PA approach, although providing a wealth of information, is most vulnerable to the retrospective reports of informants who may be biased by knowledge of the type of death of the subject of the inquiry. The PA method is also limited with regard to providing information on the subject's private self-perceptions, coping, or cognitive distortions. Such data can be obtained by interviewing persons who have survived a suicide attempt. However, attempters and completers have been described as distinct but overlapping populations (Linehan, 1986). Among younger groups, the ratio of attempts to completions is high, indicating that many more persons attempt than complete suicide, with variability in the intention for completion (Meehan, Lamb, Saltzman, & O'Carroll, 1992). In addition, women outnumber men in suicide attempts, but men exceed women in suicide completions in the general population both in the USA and the UK (Barraclough, Bunch, Nelson, & Sainsbury, 1974; Mościcki et al.,1988).

Among the elderly, however, the ratio of attempts to completions is estimated to be around 4:1 (Stenback, 1980). This has been interpreted to suggest that the elderly who attempt are more intent on completing suicide, and therefore may be more similar to completers than younger populations (Frierson, 1991; Merrill & Owens, 1990). In addition, previous studies of elderly suicide attempters find higher rates of later suicide completions relative to younger groups (Gardner, Bahn, & Mack, 1964; Kreitman, 1976a; Mościcki, 1995; O'Neal, Robins, & Schmidt, 1956). Because elderly attempters may be very similar to completers, and because studying attempters may offer valuable insight into the risk factors for late life suicide, this method would seem to be among the more promising methods to pursue to increase our knowledge about risk factors for completed suicide. In addition, elderly suicide attempters are an important group to study due to the significant morbidity and mortality that follows an attempt.

7.11.3 EPIDEMIOLOGY OF SUICIDAL BEHAVIOR IN LATE LIFE

7.11.3.1 Suicide Completions

7.11.3.1.1 Age, gender, and race

In the USA, like most other industrialized nations, the most consistent demographic factors associated with risk for suicide are older age and male gender (McIntosh, Santos, Hubbard, & Overholser, 1994; Mościcki, 1995; Pearson & Conwell, 1995). In the USA, older white males have by far the highest rate, followed by African-American men of all adult years. White females have the third highest rate among older persons, and African-American women having the lowest rate. Figure 1 illustrates these differences in rates.

A US Center for Disease Control and Prevention report declared that elderly suicides rates were on the increase (Suicide Among Older Persons, 1996). Fluctuations in suicide rates, such as these, have been the subject of cohort and period effect studies since the mid 1970s. Manton, Blazer and Woodbury (1987) examined age, period, and cohort effects separately on middle age and later life suicides; they concluded that when age and period effects were controlled, cohorts born before World War I and persons born after World War II (baby boomers) were at most risk relative to cohorts born between the World Wars. Murphy and Wetzel (1980), examining US rates from 1949 to 1974 by birth cohort, concluded that with more recent cohorts, rates were rising, regardless of race or gender, and raised an alarm that suicide rates would continue to increase in the USA unless major public health efforts were employed. Furthermore, given that the absolute numbers of the elderly will be increasing as the baby boomers age, the absolute numbers of suicides have been predicted to increase (Conwell, 1994).

However, Newman and Dyck (1988) proposed that the many national trends for "cohort effects" of increasing suicide rates could also be explained by period effects that may or may not be long-lasting. More recently, Fombonne (1994), in considering the evidence for increasing rates of depression and suicide, raised several issues that make it difficult to clearly conclude when changes in rates reflect cohort, period or age effects. These include the interaction among cohort, age and period, and the instability of effects due to selected age groupings. In studies of suicide rates, "the elderly" are often those considered age 65 and older (e.g., Kaplan, Adamek, & Johnson, 1994; McCall, 1991), but within this large age span, some age groups have shown more fluctuation or steeper rises in rates. White males age 65–69 had a suicide rate in 1980 of 30 per 100 000, and a 1993 rate of 27.8 per 100 000, which is a very slight decrease. In contrast, white males age 85 and older had a rate of 52.8 in 1980 but a rate of 73.6 in 1993, a very significant increase (National Center for Health Statistics, 1996). McCall and Land (1994) attempted to account for the increases in older suicides with social structural factors such as social security, cohort size, and widowhood. Although there was some evidence

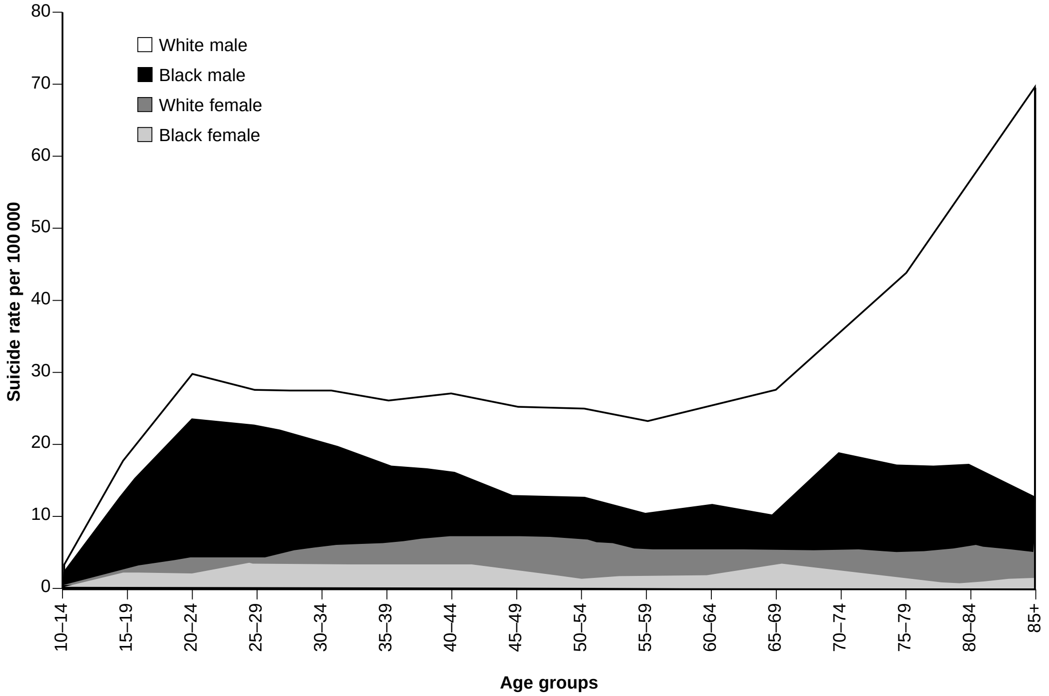

Figure 1 US suicide rates by age, gender, and racial groups, 1995. Source: National Institute of Mental Health, 1997. Data are from the Center for Disease Control and Prevention, National Center for Health Statistics.

for these factors being related to elderly suicides among the "young old" (ages 65–74), they found that none of the factors were related to suicides among the oldest old (ages 75 and older).

7.11.3.1.2 Marital status

In 1992, the rate for divorced and widowed men age 65 and older was 76.4 per 100 000. This was 2.7 times the rate for married men, and 1.4 times the rate for never-married men of this large age group (Suicide Among Older Persons, 1996). In a study comparing older widowed men and women, Li (1995) also reported that the risk of suicide for widowed men was three times greater than for widowed women over a 12 year period in a Maryland county sample. Buda and Tsuang (1990), using 1985 national statistics, reported age differences in specific rates for widowed and divorced males. Up to age 54, males who were widowed had higher rates than divorced males, but beginning with the age 55 group and higher, males who were divorced had higher rates of suicide compared to widowed males. Cohler and Jenuwine (1995) have considered the effects of age and marital status from a life course perspective. As an "off time" event, widowhood is less expected in earlier stages of life and therefore may be more stressful. This may be especially the case for men, where higher mortality rates occur during widowhood for younger men compared to younger women (Kaprio, Koskenvuo, & Rita, 1987), including suicide.

The higher rates of divorce among older men who suicided may reflect long-term family conflict or lack of supportive family interactions which increase risk for suicide. Indeed, family conflicts have been reported to play a role in elderly suicide attempts (Draper, 1994; Schmid, Manjee, & Shah, 1994; Zweig & Hinrichsen, 1993). These studies, along with the patterns of marital status and completed late life suicide rates highlight the need for more focused study on family process factors that may affect older persons' risk for suicidal behavior.

7.11.3.1.3 Methods of suicide

Death by firearms is the most common suicide method in the USA, and the elderly are more likely than any other age group to commit suicide with firearms (Kachur, Potter, James, & Powell, 1995; Kaplan et al., 1994; Meehan, Saltzman, & Sattin, 1991). Figure 2 illustrates the rate of suicides by method and by five-year age groups for 1992. Elderly males (those 65 and older) showed the most proportional increase in the use of firearms as a method of suicide from 1979 to 1992 (Kaplan et al., 1994; Meehan, et al., 1991; Suicide Among Older Persons, 1996).

Kaplan, Adamek, and Geling (1996) examined sociodemographic correlates of firearm use in white elderly male suicides from 1989 to 1991. Consistent with gun ownership patterns (Davis & Smith, 1989–1991), they found that nonmetropolitan residents and men with less than high school education were more likely to use firearms. With regard to marital status, single, never married, males were somewhat less likely than married, widowed, or divorced men to use firearms as a method.

Because efforts to reduce availability of methods of suicide have been reported to result in fewer deaths by suicide (Kreitman, 1976b; Nowers & Irish, 1988), it would seem logical that limiting access to firearms would reduce the rate of elderly suicide (Kaplan et al., 1996). For example, Dennis and Lindesay (1995) describe how a combination of limiting suicide methods on several fronts may have served to reduce elderly suicide rates in the UK. The detoxification of coal gas in the early 1960s was linked to a pronounced and prolonged drop in elderly suicides rates (Kreitman, 1976b), and restriction of prescribed barbiturates has also been associated with fewer deaths by self-poisoning in the elderly (Nowers & Irish). The introduction of exhaust emission laws led to a reduction of suicides by this method in the USA and abroad (Clarke & Lester, 1987).

Studies on the effects of reduced access to handguns and firearms have focused mainly on younger suicides. The degree to which such limitations have had significant effects remains controversial (Rich, Young, Fowler, Wagner, & Black, 1990), where rates of other methods (e.g., hanging) have been found to rise when guns (primarily handguns) are restricted. Sloan and his associates compared suicide rates between King County (Seattle) with the city of Vancouver BC, where the former has fewer restrictions on handgun ownership (Sloan, Rivara, Reay, Ferris, & Kellermann, 1990). Although persons aged 15 to 24 had higher rates of suicide by handguns in King County, the rate of death by firearms among middle-aged and elderly persons (age 45+) was virtually the same in these two communities. There has been no test of the limitations of firearms and its association with decreased suicides by firearms specifically among the elderly.

7.11.3.2 Suicide Attempts among the Elderly

Few epidemiologic studies have focused on the rates of suicide attempts in the elderly. Using data from the National Institute of

Figure 2 Percentage of suicides by age and method for 1992. From Kachur et al. (1995). Source: National Center for Health Statistics.

Mental Health Epidemiologic Catchment Area study (ECA; Regier et al., 1984), Mościcki et al. (1988) found a much lower prevalence of lifetime suicide attempts than younger populations. For persons age 65 and older, the lifetime prevalence for suicide attempt was 1.1%. In comparison, for persons age 25 to 44, the rate was 4%. There are no published ECA rates that examine older adults in smaller age groups, nor in combination with gender or race.

7.11.4 CORRELATES OF LATE LIFE SUICIDE COMPLETION

7.11.4.1 Psychopathology

The primary method for studying the psychopathology associated with suicide in late life is the PA. Structured diagnostic interviews with knowledgeable informants allow for comparisons of risk for various diagnoses. Various estimates indicate that psychiatric disorder and/or substance use were present in about 90% of suicides, with affective disorder the most common psychopathology, followed by substance use and schizophrenia (Conwell, 1994). The diagnostic profile of suicides, however, differs with age. Conwell and Brent (1995) reviewed 14 PA studies from the USA and Europe that examined psychiatric disorders across age groups. Schizophrenia, substance use, and conduct disorder are more common among younger persons, while affective disorder, primarily major depression of a late onset, is more characteristic of older suicides. In addition, the proportion of suicides associated with substance use disorders also declines with age. Although the disorders of dementia and delirium increase substantially in late life, few studies have found these diagnoses associated with risk for suicide (Conwell & Brent).

Conwell and his colleagues (Conwell, 1994; Conwell, Duberstein et al., 1996) make a strong case for late onset depression as the most powerful diagnostic risk factor for late life suicide. Conwell (1994) also cites a clinical follow-up study that illustrates this point. Gardner et al. (1964) linked psychiatric case register information with death certificates for Monroe County, New York. Age effects were considered among persons less than 55 compared to those 55 and older. Among persons with affective disorders, one year rates for suicide among the younger group were 207 per 100 000, while for the older group, the rate was 475 per 100 000.

7.11.4.2 Previous Suicide Attempts

Although elderly suicide victims are much less likely than younger victims to have a history of past suicide attempts (Conwell, 1994; Kreitman, 1976a; Merrill & Owens, 1990; Pierce, 1987), and as noted above, the elderly in general have low prevalence of lifetime suicide attempts compared to younger age groups (Mościcki et al., 1988), previous suicide attempts appears to be a potent risk factor for later completion. Although one could argue that competitive mortality and physical frailty may work to produce this effect, greater suicide intent and lethality among the elderly would suggest that these effects are not the major forces behind this pattern (Conwell). Moreover, in the clinical registry follow-up study by Gardner et al. (1964), of the persons age 54 or less who attempted suicide, 2% completed suicide within a year. In contrast, among the persons age 55 and older, 6% completed suicide in the same period. Nordentoft et al. (1993) reported more recently on a 10 year follow up of Danish patients admitted to a poison treatment center for suicide attempts, where greater age was among the significant risk factors for subsequent suicide.

7.11.4.3 Physical Illness

Several studies (Conwell, Rotenberg, & Caine, 1990; Sainsbury, 1955, Whitlock, 1978) have indicated that physical illness is a common diagnosis among elderly suicides. When making age comparisons with suicide rates, older persons are more likely to have experienced a physical illness as a “life event” relative to younger persons (Rich, Young, & Fowler, 1986). The British studies (Sainsbury and Whitlock) noted above, found that cancer, in particular, was a frequent correlate of suicide in late life. However, a case controlled study by Henriksson and his colleagues found depressive syndromes to be equally present (80% and 82%) among cancer patients who suicided (two-thirds were age 60 and older) and age- and sex-matched comparison suicides without cancer histories (Henriksson, Isometsä, Hietanen, Aro, & Lönnqvist, 1995).

Other studies have indicated that the actual rates of physical illness among elderly suicides are lower than expected. Clark (1992) reported that among 73 consecutive elderly suicides in Cook County, Illinois, only 14% were terminally ill and 23% were chronically or severely medically ill at the time of death. Given the high rate of physical illness (chronic, acute, terminal) among older persons, it is imperative to further pose this question in case controlled studies.

7.11.4.4 Personality Dimensions

Research on younger samples of completed suicides has indicated an association with personality disorders and certain personality characteristics (Angst & Clayton, 1986; Marttunen, Aro, Henriksson, & Lönnqvist, 1991; Paffenbarger, Lee, & Leung, 1994; Runeson & Beskow, 1991). Interest in personality characteristics and disorders in late life suicide may have been limited due to the challenge of assessing them through informants, as well as the belief that diagnosed personality disorders have less validity in the elderly (Sadavoy & Fogel, 1992).

Duberstein and his colleagues (Duberstein, 1995; Duberstein, Conwell, & Caine, 1994) have used an informant-based measure of the NEO-Personality Inventory (Costa & McCrae, 1985) to examine possible personality traits among older and younger suicides, relative to controls. The NEO inventory measures five general personality traits: neuroticism, extroversion, openness to experience, agreeableness, and conscientiousness. Suicides were found to have higher neuroticism scores, and older suicide victims had lower openness to experience scores than both younger suicides and normal controls. Clark (1993) has theorized that a "narcissistic" crisis, based on a personality predisposition, leaves the older person with increasingly rigid, inflexible thoughts under stressful life events.

Duberstein (1995) has theorized about the behavioral correlates of low openness to experience (OTE) with implications for clinical assessment, the possible gender differences in OTE and depression, biological correlates, and association between OTE and attempted suicide. Each of these offer important clinical implications and plausible research directions in suicidal behavior in late life.

Some reports suggest that it may be the confluence of personality, poor coping skills, fear of illness and the hopelessness of depression that influences the association between physical illness and suicide in the elderly. Conwell, Caine, and Olsen (1990) presented a series of eight cases where the victims' fears that they had cancer played a major role in committing suicide. Among these eight cases, only one was reported to have cancer upon autopsy, and five had diagnoses of major depression. Similarly, Horton-Deutsch, Clark, and Farran (1992), reporting on 14 cases from the study cited by Clark (1992) above, describe the co-occurrence of chronic dyspnea, increasing limitations in functional status, life events, and depression and anxiety among elderly men who suicided. Common to both of these studies is the description of the personality characteristics of the majority of elderly male suicides: appearance of being overtly strong and self-sufficient, yet covertly or overtly having difficulty in being dependent and accepting help, and having a rigid, inflexible coping style, not unlike a lack of OTE.

7.11.4.5 Life Events

7.11.4.5.1 Physical illness and loss

Significant age differences in recent life events among completed suicides have been reported in several studies (Rich et al., 1986; Heikkinen & Lönnqvist, 1995), where the proportion of victims with current somatic illness increases with age, and marital separations, family discord, and job problems are more common among younger suicides. When physical illness is excluded, few life events are found among elderly suicide victims. Outside physical illness, the most commonly cited life event associated with late life suicide is "loss." Loss in this context has referred to loss of spouse, family members, friends, job, physical autonomy, and impending nursing home placement (Conwell, 1994). Unfortunately, such losses are common in late life in general. Once again, without adequate control groups, it is not clear in what ways these events become risk enhancing for suicidal behavior.

7.11.4.5.2 Living alone

Another frequently cited risk factor is social isolation and living alone, which may or may not be linked to life events such as widowhood or family estrangement. Barraclough (1971) reported that among 30 suicides of persons age 65 and older, 50% lived alone, compared to 20% in the community from which they lived. More recent studies conducted in the USA have not found similar patterns. For example, Conwell et al. (1990) did not find an increase in living alone among complete suicides age 50 and older. Only 35% were found to be living alone; more than one-third of elderly suicide victims were married, and more than half lived with a spouse or family member.

Perhaps more important are the distinctions to be made among the constructs of living alone, social isolation, and loneliness. Living alone does not imply social isolation or loneliness. Younger et al. (1990) reported that among the nearly 50% of people living alone who had committed suicide, 60% had weekly visits with others outside the home and 98% had weekly contact with friends and family. The degree to which these suicide victims felt lonely, despite their contact with others, is not known and suggests the need for separating these constructs in both clinical assessment and future research.

7.11.4.6 Neurobiological Correlates

7.11.4.6.1 Serotonergic system

To date, there are still no specific biological markers for either depression or suicidal behavior. However, there are hopes that such biological information, in conjunction with psychologically assessed data, can improve detection of high risk persons, with prevention and treatment implications. If biological subtypes of suicidal behavior were to be discovered, for example, more targeted pharmacologic interventions might be developed. With regard to the elderly, it is conceivable that a "neurobiological vulnerability" to suicide might undergo modulation by age-related changes in neurobiological systems (Rifai, Reynolds, & Mann, 1992; Schneider, 1996). The consistency of suicide risk increasing with age and male gender across nations also suggests a possible neurobiological process (Conwell, Raby, & Caine, 1995). Decreased brain concentrations of serotonin, dopamine, norepinephrine and their metabolites (HVA, 5-HIAA); increased brain MAO-B activity; increased hypothalamic–pituitary–adrenal activity; and increased sympathetic nervous system activity are associated with both depression and normal aging (Schneider, 1996). Although it would seem that these correlates would have led to more neurobiological studies of elderly suicides, few have been conducted.

Several reviews have examined the evidence for neurobiologic abnormalities among elderly suicide victims relative to controls and have found too few studies that had included sufficient "elderly" subjects (older than 60 years) to draw any conclusions (Conwell & Brent, 1995; Rifai et al., 1992). This is particularly true of the subgroup of the elderly most at risk; those 85 and older. Conwell and Brent have also described the challenges to be met in obtaining sufficient cases to test various neurobiological hypotheses, and have outlined a protocol for standardization of data for postmortem research protocols.

7.11.4.6.2 Serum cholesterol

The association between serum cholesterol concentrations and late life comes from the heart disease outcomes literature. In clinical trial studies aimed at lowering serum cholesterol in persons either at risk for, or having heart disease, gains in lowered heart-related deaths have been off-set by increases in suicide and accidental deaths (e.g., Muldoon, Manuck, & Matthew, 1990). Among men age 70 and older, depression is also three times more common when plasma cholesterol concentrations are low (Morgan, Palinkas, Barrett-Connor, & Wingard, 1993). However, other studies have not found this association in free cholesterol levels, but have in the esterification of cholesterol (the reverse cholesterol transport; Maes et al.,1994). Clearly, further research in the cardiovascular and neurobiological correlates of suicidal behavior in later life are needed.

7.11.4.7 Health Service Use Patterns

Clark (1992) has noted that suicides in the USA are not higher for those with less access to health care. To the contrary, suicide rates are lower for African-Americans and Hispanics (groups who underuse health care) relative to their white counterparts. Indeed, a phenomenon common among elderly suicide completers and attempters is that the majority have recently visited a health care provider. Importantly, however, virtually none of these elderly had sought mental health services. This is in contrast to younger aged adults, where 25–30% were under the care of a mental health professional at the time of their death (Clark & Fawcett, 1992).

Instead, over 70% of older suicides have visited their primary care physician within the month of their suicide in the USA (Conwell, 1994) and the UK (Vassilas & Morgan, 1994). A similar pattern appears for elderly attempters in Japan (Takahashi et al., 1995), where more attempters relative to depressive controls sought out primary care physicians. This pattern may be in part due to physical concerns that reflect actual acute or chronic illness, as rates of comorbid physical illness among elderly suicides are also high compared to younger groups (Cattell, 1988; Conwell, 1994). This pattern may also be related to hypochondriacal concerns (Barraclough et al., 1974), and fear of pain, physical illness, and concomitant dependency as described above (Clark, 1993; Conwell et al., 1990; Duberstein, 1995; Horton-Deutsch et al., 1992).

The failure to recognize and adequately treat older adults with depression is probably due to several causes. First, the elderly themselves and their family members may incorrectly attribute depressive symptoms to the aging process, and see depression as a "normal" aspect of aging, and an expectable side effect of physical illness. Primary care physicians tend to spend less time with older patients and focus on physical problems to the exclusion of mental morbidity (German et al., 1985; Keeler, Solomon, Beck, Mendenhall & Kane, 1982). Second, there may be hesitancy or inability to report psychiatric symptoms even when specifically asked. Gallo, Anthony, and Muthén, (1994) have found that older depressed adults are less likely to endorse dysphoric mood as part of their symptom clusters. Older men, in particular, are less likely to report depressive symptoms (Allen-Burge, Storandt, Kinscherf, & Rubin, 1994; Lutsky & Knight, 1994). Third, primary care physicians, who are the most sought after health care providers among all persons with depression in the USA, typically do not recognize (e.g., Perez-Stable, Miranda, Munoz, & Ying, 1990) nor adequately treat depression among any age group (Sturm & Wells, 1995).

7.11.5 STUDIES OF ELDERLY SUICIDE ATTEMPTERS

Given the limited data on the epidemiology of late life suicide attempts, the bulk of this discussion focuses on studies of hospital based samples. In a review of attempted suicide in late life, Draper (1996) reviewed 12 studies published between 1985 and 1994. Despite variation in sampling contexts and approaches to measurement, and lack of adequate control groups, there were several consistent factors associated with attempted suicide in late life: depression, social isolation, and being unmarried. The degree to which physical health was a risk factor was unclear; in some studies it appeared to play a major role (Draper, 1994; Frierson, 1991; Nowers, 1993), while in another only about a third of the patients identified health as a factor (Pierce, 1987). Draper suggested that the interaction between psychosocial factors such as social isolation, loneliness, family conflict, and physical factors such as presence of pain and perceived limitations may be a more critical combination for risk of suicide attempt than physical illness alone. A gender difference by age pattern was also noted across the studies: the proportion of males attempting suicide increased with age, particularly among those age 75 and older. Without adequate control groups, however, these findings remain interesting leads rather than true advances in our understanding of risk factors for suicide attempts in late life.

Among the few studies with control groups, elderly depressives admitted for a suicide attempt have been more likely to have a later age of onset than elderly depressives who were not suicidal (Lyness, Conwell, & Nelson, 1992). In a German study an age by sex interaction in age of onset was noted, where men age 50 and older were more likely to have had an affective illness of late onset, and women had a younger age of onset and were more likely to have had previous suicide attempts (Bron, Strack, & Rudolph, 1991).

Psychosis and somatization have characterized the psychiatric symptoms of elderly suicide attempters. Lyness et al. (1992) and Roose et al., (1983) found psychotic depression to be more related to suicidal behavior than other affective disorders in retrospective cohort studies. Psychotic depression is interpreted by some to include delusions about physical symptoms. In a Japanese study of urban elderly attempters, Takahashi et al. (1995) examined the rates of somatization (defined as a separate entity from depression) among attempters and controls. Consistent with earlier descriptive studies of high rates of hypochondriasis among elderly attempters (Barraclough et al., 1974; De Alarcon, 1964), they found higher rates of somatization among attempters relative to controls. Although somatization can be defined as a type of psychosis, its unique role and cooccurrence with depression in late life appears worthy of further investigation.

7.11.6 SUBGROUPS OF ELDERLY AT RISK FOR SUICIDE

Suicide is a multidetermined, low base rate event. Despite the many correlates and posited risk factors identified, the prediction of suicidal behavior is next to impossible (Goldstein, Black, Nasrallah, & Winokur, 1991; Pokorny, 1983). However, since suicide risk in the elderly is strongly associated with certain demographic (white males) and psychological variables (depressive diagnoses and rigid coping), it follows that certain subgroups of the elderly are more or less likely to be at risk for suicidal behavior. The primary intent of proposing subgroups here is to stimulate research questions that consider the interaction of such demographic characteristics with other known risk or protective factors that may help the field move beyond studies that focus on main effects.

7.11.6.1 Intolerance for Physical Illness or Dependency

The discussions of somatization and findings pertaining to the role of physical illness in elderly suicide would suggest that there are persons, who, when faced with what they perceive to be an illness that may limit autonomy, become risks for suicide. White males, living in the community, who have taken pride in being independent and self-sufficient would be the prototype of this subgroup. Stated fears of losing what are considered markers of independence, such as driving or living independently, may reflect underlying intolerable anxiety and depression. These fears, in combination with suspicion of having an incurable illness with functional limitations, may create a lethal combination. In contrast, studies of patients with terminal illnesses, who have learned to readjust their expectations about life have a lower risk of suicidality (Marshall, Burnett, & Brasure, 1983). Measures of hopelessness (Beck, Brown, Berchick, Steward, & Steer, 1990; Beck, Steer, Kovacs, & Garrison, 1985; Hill, Gallagher, Thompson, & Ishida, 1988; Rifai, George, Stack, Mann, & Reynolds, 1994), limited openness to new experience (Duberstein, 1995), perfectionism (Hewitt, Flett, & Turnbull-Donovan, 1992), and willingness to adapt may help screen those elderly with physical illness who may be at risk for depression and suicidal ideation.

7.11.6.2 Older Alcoholics

Another group at risk for suicide are older male alcoholics with early onset who have survived to be among the "young old." Murphy and his associates described a number of factors associated with suicide among alcoholics. For the older male alcoholics, loss of the last social support has been found to be a pivotal event in suicide risk (Murphy, Wetzel, Robins, & McEvoy, 1992). Similarly, Duberstein et al. (1994) reported that interpersonal stressors and recent alcohol use combined to increase risk for suicide. In a Finnish sample, Heikkinen et al. (1994) compared nonalcoholic depressives and alcoholics who had committed suicide. Unlike depressives, alcoholics were likely to have recent interpersonal loss, unemployment, and financial trouble. Drinking patterns appeared to lead to these concurrent stressors. Assessment of depression as well as current social support among older alcoholics would seem to be essential in understanding risk for suicidal behavior in this subgroup.

7.11.6.3 Immigrants and Ethnic Minority Elderly

Studies conducted in Hong Kong (Yap, 1958), Singapore (Ko & Kua, 1995), Australia (Burvill, 1995); Burvill, Woodings, Stenhouse, & McCall, 1982), and Canada (Kliewer & Ward, 1988) indicate that suicide rates are higher among immigrants than natives of the host country. Such research is complicated as it must consider factors that may influence suicide risk in the country of origin (e.g., religion, the individuals' reason for leaving and mental health history); factors within the country of migration; and the society of settlement (e.g., similar or different in ethnicity, and degree of acculturation) (Murphy, 1977). With regard to elderly suicide, the study of these factors are even more challenging to consider as age of immigration can vary widely (e.g., the elderly migrant may have emigrated within the year of suicide, or 80 years prior), and familial networks will vary with the degree to which acculturation is desired or avoided. Despite these challenges, research on elderly suicide in countries and cities where immigration is high (e.g., USA, Hong Kong, Australia), comparing immigrant groups of varying rates of suicide, may help explicate the role of culture, religion, and family interactions in suicidal risk in the elderly (see Corin, 1995).

Very little empirical data exists about the risk or protective factors for suicidal behavior among African-American, non-white Hispanic, and Asian ethnic minority groups in the USA. However, theory development about risk and protective factors among ethnic minority Americans can be found (Griffith et al., 1989; Sorenson & Golding, 1988). Studies on the risk for depression in older ethnic minorities should provide clues as to risk for suicidal behavior in later life (e.g., Baker, 1996). As the number of American ethnic minority elderly are projected to increase substantially in numbers in the next few decades (US Bureau of the Census, 1996), much must be learned to best assess and treat suicidal behavior in these subpopulations in order to adequately provide care and service in the future.

7.11.6.4 Older Women

A fourth subgroup needing further study are elderly women. Canetto has discussed what is known about gender issues in suicide, including what little is known about older female suicides (Canetto, 1992, 1994, 1995). Of the many sociologic risk factors proposed to increase risk for suicide, including retirement, financial stress, widowhood, living alone, and poor physical health, older women suffer more than older men in each of these categories, yet have lower suicide rates (Canetto, 1995). Moreover, of the mental disorders thought to increase risk for late life suicide, depression is the most frequent disorder cited and older women have higher rates of depression than older men (Kennedy et al., 1989; Livingston, Hawkins, Graham, Blizard, & Mann, 1990; Romanoski et al., 1992), as well as more functional impairment with depression (Kornstein, et al., 1995).

Because of these contradictions, Canetto has recommended that discussions of elderly suicide become more precise with regard to gender. Clearly, applying typical risk factors that reflect older male suicides in studies of older women will not yield great benefits. What may be of more utility is to examine gender differences in acceptability of completed suicide as a behavior (Canetto, 1995), as well as examining gender differences in coping and cognitive styles. Rumination, a cognitive style more common among women, may prolong depressive episodes and serve to increase prevalence rates (Nolen-Hoeksema, 1987; Nolen-Hoeksema, Morrow, & Fredrickson, 1993). Interpersonal sensitivity and a relational interactional style more common among women (Markus & Oyserman, 1989) makes them more sensitive and responsive to others' problems. Although this gender-typed style may contribute to prolonged depressive episodes among women, it may also protect them from acting on suicidal thoughts (Canetto, 1992). Little is known about how interpersonal sensitivity or a ruminative cognitive style are related to depression or suicidal ideation in older women, or what mediating factors such as social support influence these possible associations.

With regard to the older women who do complete suicide, one could hypothesize that older female suicides have had more previous attempts, based on epidemiologic data of middle-aged populations (Mościcki et al., 1988). Higher rates of previous attempts is also related to borderline personality disorder and less lethal attempts (Rich et al, 1986; Runeson & Beskow, 1991), which also are more common among women. Nolen-Hoeksema (1995) has articulated the biological and psychosocial theories of the evolution of gender differences in depression. There is evidence to suggest that some of the factors that increase rates for depression in women are similar to those for suicidal behavior, particularly histories of abuse in childhood and adulthood (Davidson, Hughes, George, & Blazer, 1996; Kaplan, Asnis, Lipschitz, & Chorney, 1995).

7.11.6.5 Nursing Home Patients

If nursing home settings are considered (where the vast majority of residents are female), less lethal and more passive attempts, such as refusal of food or adherence to medications may characterize suicidal behavior in this subgroup. Indeed, Osgood surveyed long-term care facilities and reported that most self-destructive behaviors in nursing homes were indirect, and that setting characteristics were related to rates of self-destructive behavior (Osgood, 1992; Osgood & Brant, 1990). Building on this work, Conwell, Pearson, and DeRenzo (1996) have summarized several research issues on self-destructive behaviors in nursing home patients. Included are patient-related factors (psychiatric illness, physical health, personality and coping styles, religious beliefs, and neurobiological beliefs), setting influences (nature and size of facility, quality of care provided) and their interactions, as well as ethical issues involved. Given the high prevalence rates of mental disorders in nursing homes that go undetected and untreated (Rovner, Kafonek, Filipp, Lucas, & Folstein, 1986; Strahan, 1991), the need for further study of self-destructive behavior, both direct and indirect, is clearly needed in these settings.

7.11.7 BIOETHICAL ISSUES

7.11.7.1 Physician Assisted Suicide

The question of risks for suicidal behavior in nursing homes brings to the surface the many complicated issues involved in passive and active euthanasia, advance directives, and physician-assisted suicide (see Chapter 6, this volume). Although there is consensus that decisions regarding the limitation of life-saving procedures are not "suicidal" in terminal illness, such as requesting do-not-resuscitate orders as a part of acute health care treatment, the role of the physician to hasten the process by active means remains controversial. The US public, health care guilds, and health care providers continue to debate patients' rights and physician-assisted suicide and in some cases, act on their beliefs (e.g., see Gibbs, 1993 on Kervorkian; Quill, 1991). In March 1996, the 9th US Circuit Court of Appeals (Compassion in Dying vs. State of Washington, 1996) ruled that *mentally-competent, terminally-ill* adults have a constitutionally protected liberty interest in hastening what might otherwise be a protracted, undignified and extremely painful death. The guiding principle here is that of patient autonomy. Patients have the right to control their own bodies and to decide for themselves the course of their own medical treatment.

The salience and complications of these issues vary with the health care context, perspective and health status of the patient, and age and perspective of the clinician (Marks, 1988–1989). Among adults with terminal illnesses who are cognitively intact, refusal of treatment or requests for physician-assisted suicide appears less controversial. With regard to the elderly, many of whom may not be competent to advocate for themselves, or may or may not have family members who can be trusted to represent their wishes, the issue is very controversial (Osgood, 1995). Competency is a pivotal issue, because cognitive impairment and depression often co-occur with terminal illness. Sullivan and Youngner (1994) highlight differences in clinicians' views on competency in the elderly by examining the refusal of life-sustaining treatment by patients with serious medical illness and comorbid depression. In medical settings, competence to refuse life-sustaining treatment is typically presumed unless the physician proves otherwise. In psychiatric settings, a desire to die is considered evidence of a mental disorder and proves justification of treatment.

7.11.7.2 Competency and Depression

Sullivan and Youngner (1994) recommended that depression in medical patients be treated to improve competency. If treatment is not successful, a residual diagnosis of depression is neither necessary nor sufficient for determining that the patients' medical decision is impaired. In their argument, depression and competency are separate issues. Yet others argue that depression can render limitations on consciousness, where alternatives other than suicide cannot be clearly considered by the patient (Clark, 1992; Koenig, 1993). Shneidman (1986) represents this same sentiment in his assessment of the cognitive narrowing and inflexibility of the suicidal patient: "It is not a thing to do while one is not in one's best mind. Never kill yourself when you are suicidal" (p. 8).

Studies on how depression affects decision making in late life are limited, but some evidence suggests that depression can affect the consistency in preferences for end of life decisions. Lee and Ganzini (1992) studied elderly persons seeking medical treatment, and found mild to moderate depression not to affect preference for life-sustaining medical therapy (intravenous fluids with medications, feeding tube, blood transfusions, intensive care, kidney dialysis, ventilatory support, and cardiopulmonary resuscitation). Among severely depressed elderly, however, there was less consistency in preferences over time. Lee and Ganzini (1994) have also documented little consistency among depressed older medical inpatients who recover from their depression. When depressed subjects who recovered changed their preferences, they were as likely to change from refusing to desiring a treatment as vice versa. Those who became depressed, and remained depressed, were likely to refuse an intervention they had initially asked for.

Sullivan and Youngner (1994) have argued that studies of nursing home residents provide equivocal evidence for the effects of depression on life-sustaining treatments, where depression in patients has been related to both decreased and increased desire for life-sustaining treatments (Garrett, Harris, Norburn, Patrick, & Davis, 1993) compared to preferences among nondepressed residents. What may contribute to inconsistencies in findings may be the mixing of research methods (hypothetical future illness versus current state of illness). Attempting to draw comparisons across diverse groups of elderly may be misleading due to the demographic and health differences among the elderly: community elderly seeking medical care are likely to differ significantly from nursing home residents with regard to age, gender, general health status, and perspectives on death.

Consistent with Lee and Ganzini's work, along with commonly found risk factors for late life suicide (male gender, white ethnicity), other evidence suggests that older persons' attitudes towards suicide may be related to their perceived social support and health and mental state (i.e., depression). Seidlitz, Duberstein, Cox, and Conwell (1995), using data from a Gallup Poll, found that nonreligious white men, especially those with strained family relationships and self-perceived failing health, were the most likely to endorse lenient attitudes toward suicide. Although owning such an attitude does not predict suicidal behavior, it does lower the threshold for tolerance of this option. Moreover, since lenient attitudes towards suicide may reflect hopelessness about family relations and self-perceived health—aspects that may be subject to change with intervention—treatment of depression or anxiety among patients holding such attitudes may affect lenient attitudes toward suicide.

7.11.7.3 Bioethical Research Needs

Future research that considers both patient-related and setting influences may help reconcile the seemingly contradictory evidence regarding depression, end-of-life decisions, and suicide. In considering these issues in the nursing home setting, Conwell, Pearson, and DeRenzo (1996) identified five patient-related factors relevant to self-harming behaviors: assessment of psychiatric symptomatology (dementia, depression, hopelessness, suicide intent, ideation); physical health (including somatic complaints and pain); personality and coping style (rigid coping style, openness to experience); religious beliefs; and neurobiological influences. Although setting influences described by Conwell, Pearson and DeRenzo (1996) were directed towards nursing homes, the context of access and willingness to seek health care, social supports, and attitudes of family members and health care providers can be assessed among the hospitalized and community dwelling elderly, and should be factored in the investigations of the individuals' decisions about end-of-life decisions.

An important implication of implementing right to refuse treatment policies or enacting physician-assisted suicide laws may be how such options affect older persons' attitudes about suicide. Increased availability and use of hospice care could conceivably affect older persons' attitudes towards suicide. If the end of life seems less likely to be characterized by pain, suffering, and dependence, dying by a "natural course" may seem more tolerable, and suicide a less preferred suicide option (Amenta & Shubert, 1995). For others, physician-assisted suicide may hasten death and reduce the time of enduring intolerable pain and suffering. Posner (1995) has argued that the perception that physician-assisted suicide can be available as needed, could be an effective means of suicide prevention in later life. These are researchable issues that can and should be addressed to best inform legislators and policy makers.

7.11.8 CLINICAL RESOURCES FOR TREATING SUICIDAL OLDER ADULTS

Suicide is an attempt to solve a problem of unbearable psychological pain, where few alternative solutions are seen or considered by the patient (Shneidman, 1992). The inability to consider that solutions, even though not obvious now, may be present in the future, reflects the serious hopelessness felt by suicidal patients (Beck et al.,1990; Beck et al., 1985; Rifai et al., 1994). Aspects of approaches to suicidal patients that appear particularly applicable to the elderly include the assessment of what Shneidman termed "cognitive constriction" (Shneidman, 1985). Constriction can be defined generally as dichotomous thinking, tunnel vision, or a narrowing of the range of options. As long as alternative solutions are not seen as plausible, suicide as a viable option remains and risk for acting on suicidal ideation is high. Clinical interventions for suicidal persons, whether they are individual, family, group, or pharmacologic in nature, must be effective in providing the alternative solutions to suicide.

As multiple psychological autopsy studies have shown, more than 90% of cases of adult suicides have had a recent major psychiatric disorder (Clark & Fawcett, 1992). Moreover, the lifetime probability of suicidal death is 15% for persons with a major affective disorder (Klerman, 1987). Therefore, the prevention of suicide in late life in both a crisis situation, and in the long run, will be best accomplished by the increased recognition and adequate treatment of depression (NIH Consensus Conference, 1992). As such, most of the clinical resources suggested below address treatment of depression primarily, with secondary benefits to reducing risk for suicide.

Unfortunately, there are few studies that address the effectiveness of various interventions with suicidal persons in general, and virtually none focusing on the elderly. Crisis hotlines are nearly impossible to evaluate (Lester, 1993), and little information exists on the elderly's use of such services in the USA (Conwell, 1994). Adamek and Kaplan (1996), in a survey of American Association of Suicidology listed crisis prevention centers, found that even though about a third had specialty programs for the elderly or specific outreach efforts, two-thirds of the staff did not know that older adults are the age group with the highest suicide rate. Although crisis lines may not be effective with the elderly, telephone outreach programs do show some promise of reducing psychological distress and suicidal ideation, if not completed suicide (see McIntosh, 1995, for a review).

With regard to comparative interventions with suicidal elderly, no studies exist, highlighting the need for this type of research. Therefore, the clinical resources described below are not proven to be effective treatments, but do reflect the state-of-the-art and limited science.

7.11.8.1 Psychotherapeutic Resources

There are a growing number of guidelines and descriptions of psychotherapeutic approaches to suicidal outpatients (e.g., Bongar, 1992; Leenaars, Maltsberger, & Neimeyer, 1994). Increasingly among these guidelines are articles, chapters, and even books, devoted solely to the suicidal elderly (e.g., Lester & Tallmer, 1994; McIntosh, et al., 1994; Richman, 1993). The most frequent author of chapters and papers on psychotherapeutic approaches to suicidal elderly is Joseph Richman, a family therapist who integrates research findings with nearly 30 years of clinical experience with suicidal elderly

(Richman, 1996). Richman's approach typically includes the family as well as the patient, as he considers the family an important context of the older person. The family can both contribute to the risk, and to the treatment of the suicidal elderly. His book, *Preventing elderly suicide,* reviews research that he has grounded his approach in, assessment, crisis intervention, and individual, family and group modalities (Richman, 1993).

Cognitive-behavior therapy has also been used successfully to treat suicidal persons (Beck, Rush, Shaw, & Emery, 1979; Beck & Weishaar, 1990), including the elderly. Generally described, cognitive behavior therapy, as applied to the suicidal individual, identifies the dysfunctional beliefs that are typically helpless and hopeless in character, the feelings associated with the beliefs, and then directs the client to problem solving methods. By forming a more precise description of the problem separate from depressed mood, breaking down the problem into components, and considering possible solutions, suicide as an only option begins to dissipate. DeVries and Gallagher-Thompson (1994) have described how this approach can be applied specifically to older adults in crisis, including suicidality.

Maltsberger (1991) applies a more psychoanalytic, "ego deficit" model of suicide in the elderly, where the suicidal person is narcissistically vulnerable, fearing loss of mental and physical capacity, as well as abandonment. If the older patient is unable to ask or obtain support for these functions and self-contempt and anxiety increase, the risk of suicide increases. In this approach, the therapist can play a critical role during this narcissistic crisis by providing resources through his or her warmth, encouragement, and availability.

7.11.8.2 Pharmacologic and Electroconvulsive Therapies

7.11.8.2.1 Pharmacologic therapies

Serotonergic abnormalities in patients who are suicidal would suggest that treatments using serotonin reuptake inhibitors (SSRIs, e.g., fluoxetine, paroxetine, sertraline) would be effective (Montgomery, 1993). Since the SSRIs are just as effective as the earlier tricyclic antidepressants but have lower side-effect profiles among the elderly (Schneider, 1996), acceptability and treatment compliance with SSRIs among the elderly may be improved. Furthermore, because fluoxetine has been shown to decrease suicidal ideation relatively early in treatment among adults ages 18–65 (Worthington et al., 1995), its use with older suicidal adults may be life saving. Although there is no research pointing to particularly effective pharmacologic treatments for suicidal elderly, there are several reviews that describe the many effective pharmacologic approaches to treating late life depression (Hay & Hay, 1996; Kennedy, 1996; Salzman, 1994). More studies that track the presence and change and continuity of suicidal ideation over time of treatment and follow-up are also needed (see Rifai et al., 1994 for one example).

7.11.8.2.2 Electroconvulsive therapy

Electroconvulsive therapy, although still controversial, can be an extremely effective treatment for elderly patients with depression who are not able to tolerate the side effects of pharmacotherapies. Moreover, it is often effective where patients have not responded to traditional pharmacologic interventions. The speed of onset of its action, which is typically more efficient than medication, also makes it an indicated treatment for suicidal persons and those with severe depressions in late life. The efficacy, applications, adverse effects, and contra-indications for use in the elderly have been reviewed elsewhere (Hay & Hay, 1996; Sackheim, 1994). Although there are no outcome studies specific to suicidal elderly, Avery and Winokur (1976, 1978) have demonstrated that electroconvulsive therapy does decrease the number of suicidal outcomes in depressed patients.

7.11.9 SUMMARY

Suicide among the elderly is one of the most critical public health problems facing us today. We have sufficient information on what appear to be strong correlates if not risk factors to address several levels of preventive interventions (Conwell & Duberstein, 1995; Rihmer, 1996). Although suicide in the elderly as a public health problem has probably been ignored due to agism, like other areas of psychopathology in late life, clinical, research, and policy interests in late life suicide (Suicide and the elderly: A population at risk, 1996) have grown with the increasing numbers of older persons in the USA, and other countries. Perhaps current older cohorts and younger cohorts will become more active in their interests in maintaining and increasing their own well-being (McIntosh, Pearson, & Lebowitz, 1997). As "baby boomers" age and demand more and better health care, the interest in the prevention and treatment of psychopathology of later life will certainly grow. It is hoped that this chapter has provided some useful groundwork, and has raised some potentially important research directions for the much needed information that will be required to meet the future needs and interests of the aging population and their family members.

ACKNOWLEDGMENTS

Dr. Paul Duberstein provided invaluable suggestions and comments on this chapter. His expert advice and criticism is greatly appreciated.

7.12.1 INTRODUCTION

7.12.1.1 Evolution of the Diagnoses

Personality disorders (PDs) have been defined as long-standing and long-lasting maladaptive behaviors that seriously impair an individual's ability to perform adequately in a variety of settings including social, occupational, educational, and interpersonal. They have also been called character disorders, and one classic hallmark of the diagnosis has been that the patients are typically unaware or unperturbed about their disorder. Although anecdotal and literary descriptions of individuals who may have had PDs have been with us for thousands of years, the official diagnosis of PDs as a unique and separate diagnostic entity did not officially appear until 1952 with the publication by the American Psychiatric Association (APA) of the *Diagnostic and Statistical Manual of Mental Disorders (DSM).*

7.12.1.1.1 Diagnostic and Statistical Manual of Mental Disorders

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-I*; APA, 1952) contained seven major diagnostic categories including one named "Personality disorders." PDs were defined as developmental defects or pathological trends in the personality, with little or no sense of subjective distress. They were thought of as lifelong patterns of behavior and not likely to go into remission. Of the 12 PDs in *DSM-I,* four were "cardinal" types, (inadequate, schizoid, cyclothymic, and paranoid) indicating that individuals were rarely, if ever, altered by therapy; four were personality trait disturbances (emotionally unstable, passive–aggressive, compulsive personality, and an "other" personality trait disorder); and finally, four were types of sociopathic personality disturbance (antisocial, dyssocial, sexual deviation, and addiction).

The *DSM-I* descriptions for all 12 main types of PD consisted of, at most, two paragraphs and, most typically, four or five sentences. Although these types provided a major evolution in the diagnosis of PDs, psychological tests for the assessment of PDs lagged for more than 25 years. The *DSM* was widely used and no rival system existed in the USA. The international World Health Organization had produced the only worldwide alternative to the *DSM* and that was the *International Classification of Diseases (ICD),* which included a section on mental disorders. The eighth edition *(ICD-8)* was approved in 1966 and published in 1968. The second edition of the *DSM (DSM-II)* was published in 1968, and was then aligned with the *ICD-8*.

7.12.1.1.2 DSM-II

The *DSM-II* (APA, 1968) listed 10 specific types of PD. Their general description was very brief (two sentences only): "This group of disorders is characterized by deeply ingrained maladaptive patterns of behavior that are perceptibly different in quality from psychotic and neurotic symptoms. Generally, these are lifelong patterns, often recognizable by the time of adolescence or earlier." The 10 specific PDs were as follows: paranoid, cyclothymic, schizoid, explosive, obsessive compulsive, hysterical, asthenic, antisocial, passive–aggressive, and inadequate. One subtle change between *DSM-I* and *DSM-II* was the simple addition that PDs are recognizable by adolescence or earlier; *DSM-I* had mentioned that PDs tended to be lifelong, but there was no mention of when the onset occurred. Both the *DSM-I* and *DSM-II* noted the chronicity but neither noted any changes in PDs as a differential function of lifespan, or type of PD as a function of age.

7.12.1.1.3 DSM-III

The diagnosis of PDs took a quantum leap with the publication of *DSM-III* (APA, 1980). Its diagnostic, paradigmatic center shifted from a psychoanalytic to a more behavioral perspective. It also became multiaxial: major clinical syndromes and symptoms were to be coded on "Axis I" while PDs were to be coded on "Axis II." Also, a specific list of numbered criteria was presented for each PD, and patients had to meet a specified minimum number of criteria before receiving a diagnosis. *DSM-III* also mentioned aging as a factor. It stated "The manifestations of Personality Disorders are generally recognizable by adolescence or earlier and continue throughout most of adult life, though they often become less obvious in middle or old age" (p. 305). For the first time, in the history of the *DSM*, it was hypothesized that PDs may diminish with age.

Another interesting aspect of PD diagnosis in *DSM-III* was that they were grouped into three clusters. The odd or eccentric cluster comprised paranoid, schizoid, and schizotypal types. The dramatic, emotional, or erratic cluster contained histrionic, narcissistic, antisocial, and borderline types. The anxious or fearful cluster was composed of avoidant, dependent, compulsive, and passive–aggressive types.

Overall, *DSM-III* listed 11 specific PDs. Only four of these had remained essentially unchanged from the earlier editions. These were the paranoid, schizoid, antisocial, and passive–aggressive types. Two PDs had name changes (histrionic was formerly hysterical, and compulsive was formerly obsessive compulsive). Four specific disorders were eliminated: cyclothymic, inadequate, explosive, and asthenic. Five new PDs were also added since *DSM-II*: schizotypal, narcissistic, borderline, avoidant, and dependent.

7.12.1.1.4 DSM-III-R

A revised edition of *DSM-III* appeared only seven years later (APA, 1987). The 11 PDs remained, and again they were coded on axis II.

The odd or eccentric cluster of PDs from *DSM-III* officially became "Cluster A" in *DSM-III-R* and still comprised the paranoid, schizoid, and schizotypal types. There were also changes to the criteria for determining each type, although each PD diagnosis still consisted of a group of polythetic criteria. The dramatic, emotional, or erratic cluster became "Cluster B" and still consisted of the histrionic, narcissistic, antisocial, and borderline types. The anxious or fearful cluster became "Cluster C" and still consisted of the avoidant, dependent, and passive–aggressive types. The compulsive PD of *DSM-III* remained in Cluster C but was renamed the obsessive-compulsive PD. That change was highly ironic since in *DSM-I* it was the compulsive PD, in *DSM-II* it was the obsessive-compulsive PD, and in *DSM-III* it was again the compulsive PD. *DSM-III-R* also included two new and potentially controversial PDs that were placed in Appendix A for diagnostic categories needing further study. These were the sadistic and self-defeating types.

In terms of aging and developmental issues, *DSM-III-R* essentially repeated the same hypotheses as *DSM-III*, that is, PDs are generally recognizable by adolescence or earlier, continue through most of adult life, and become less prominent with age. These hypotheses were far too simplistic, however, and raised many more questions than they answered. For example, did all PDs diminish with increasing age? This certainly does not appear to be the case, at least intuitively, for the schizoid and avoidant PDs. Also, why do some PDs diminish with age? Is it simply an artifact of activity level or sociability, or is the phenomenon more complicated, that is, does the abnormal behavior diminishment associated with aging reflect underlying changes in neural substrate or chemical neurotransmitter functioning in the brain?

7.12.1.1.5 DSM-IV

The *DSM* was revised and published again after a further seven year interval (APA, 1994). This edition contained only 10 PDs on Axis II. The passive–aggressive PD was removed from Cluster C and was placed in Appendix B (for further study). An alternative name, negativistic PD, was given to the passive–aggressive PD. A new PD appeared in Appendix B, the depressive PD. The sadistic and self-defeating PDs were dropped completely from the diagnostic manual. The current list of PDs in *DSM-IV* is as follows: Cluster A—the odd or eccentric (paranoid, schizoid, schizotypal); Cluster B—the dramatic, emotional, or erratic (antisocial, borderline, histrionic, narcissistic); Cluster C—the anxious or fearful (avoidant, dependent, obsessive-compulsive); and Appendix B—criteria sets and axes provided for further study (depressive, passive–aggressive [negativistic]).

7.12.1.2 Age and the *DSM*

DSM-IV was the first version of the manual to include a specific section (along with cultural and gender topics) on the developmental issue of aging in the diagnosis of PDs. Again it recorded that a PD is usually recognized by adolescence or early adult life, and, by definition, the onset of a PD must occur before middle age for an official diagnosis to be made although, of course, an actual diagnosis might not be given until later adult life. Also noted in *DSM-IV* is that a PD may be exacerbated by social upheaval, such as the loss of a spouse or a job, although a clear change in personality in middle age or later adult life would more likely be due to a medical condition or substance-related disorder. Since, and again by definition, PDs are "enduring patterns of thinking, feeling and behaving" (APA, 1994, p. 632) they were also hypothesized to be consistent and stable throughout adulthood. However, the *DSM-IV* also noted that the antisocial and borderline PDs "tend to become less evident or to remit with age, whereas this appears to be less true for some other types (e.g., obsessive compulsive and schizotypal PDs)" (p. 632). Empirical research, however, in support or against these latter specific hypotheses has been scarce.

7.12.1.3 Dimensional vs. Categorical Classification

The diagnostic philosophy contained within *DSM-IV* is that PDs are distinct clinical categories or syndromes. Theoretically, these clinical syndromes form discrete entities of abnormal behavior patterns, and again, theoretically, they would be unrelated to normal personality dimensions, for example, the extraversion–introversion dimension. Currently, a more attractive and parsimonious theory is the dimensional diagnostic approach to PDs in which the PDs are viewed as maladaptive variations of normal personal traits. Thus, in the dimensional classification approach, normal and abnormal personality behaviors are simply points along a behavioral continuum. Typically, the extreme points at either end of a continuum might be reflective of a PD. For example, an extreme extrovert might be characteristic of the histrionic PD while an extreme introvert might be characteristic of a schizoid PD.

In the late twentieth century, dimensional trait research approaches have focused on finding the number of factors minimally required to describe an individual's personality, and whether those same dimensions can describe both normal and abnormal behavior. Eysenck (1978) originally proposed a two-factor model, extroversion and neuroticism, and then expanded his model to include a third factor, psychoticism. His model clearly covers the abnormal personality, although perhaps at the expense of normal personality constructs.

The most famous model of personality is that of Carl Jung from 1924 (1971). He conceptualized the personality as being fourfold: (i) one's preference to focus on the inner or outer world, (ii) how one perceives or acquires information, (iii) how one makes decisions, and (iv) how one orients one's self towards the outer world. This model was operationalized in a psychometric test, the Myers–Briggs Type Indicator (Myers, 1962), with four bipolar dimensions: (i) extraversion–introversion, (ii) sensing–intuiting, (iii) thinking–feeling, and (iv) judging–perceiving. This model, however, appears to be biased oppositely to Eysenck's model. The Myers–Briggs model appears to be more useful in explaining the normal personality rather than the abnormal one.

Norman (1963) developed and organized a pool of 2800 personality descriptors into sets such as states, traits, and roles. Based on his work, McCrae and Costa (1986, 1989) began a prodigious flow of research into a five-factor model describing both normal and abnormal personality; specifically, this included neuroticism, extraversion, openness, agreeableness, and conscientiousness. However, their model has been criticized for lacking diagnostic utility with regard to the *DSM-IV* PDs, for being unclear as to whether they were describing five, six, or even seven factors to account for PDs (Coolidge et al., 1994), for a lack of empirical research to support their claim that their model accounts for abnormal behavior, and the overgeneralization from statistical techniques (Millon & Davis, 1996). Furthermore, Kernberg (1996) wrote: "To develop factorial profiles for each personality disorder on the basis of those five factors has an eerie quality of unreality for the experienced clinician" (p. 107).

Cloninger (1987) originally proposed a three-factor model of personality based on three brain neurotransmitters: dopamine, serotonin, and norepinephrine. Later, he expanded his model to seven factors, operationalizing the measurement of his model with the Temperament and Character Inventory (TCI; Cloninger 1986, 1987; Cloninger, Przybeck, Svrakic, & Wetzel, 1994). This theory will be discussed further later in this chapter. By contrast, Cattell identified 16 source traits from data that he identified from surface traits, and he operationalized his theoretical personality structure into the Sixteen Personality Factor Questionnaire (16PF; Cattell, Saunders, & Stice, 1950). The 16PF has been a popular instrument in personality research, although more popular in nonclinical, rather than clinical, settings.

Thus, although *DSM-IV* approaches clinical diagnoses from a categorical perspective, most empirical personality research of abnormal behavior, particularly PDs, has entailed the use of dimensional models, typically ranging from 3 to 16 core factors or personality traits. However, little research has been devoted to how aging might affect these core traits and concomitant behaviors.

7.12.2 ETIOLOGY

Enduring, inflexible, and pervasive patterns of maladaptive behavior, coupled with an early onset, suggest that PDs may have an inheritable component. Thus, most conceptions about the etiology of PDs are based upon both biological and environmental contributions, although the theories vary in the emphasis placed upon these two components. Four major etiological theories, reflecting these ideas, will now be reviewed.

7.12.2.1 Rutter's Theory of Temperaments, Personality, and Personality Disorders

Rutter (1987) noted that temperaments are hypothesized to be biologically inherited predispositions for behaving in particular ways, and they emerge early in life. He specifically hypothesized, that temperaments were limited. According to Rutter, there are not a particularly large number of temperaments influencing behavior; such temperaments are nonmotivational and noncognitive. The search for the core number of temperaments may parallel the search for the core number of personality traits or factors, with the number varying from as few as three to as many as 16. There is a fairly substantial body of empirical research in support of heritability of temperaments and their enduring influence on behavior (e.g., McGue, Bacon, & Lykken, 1993; Plomin, Chipuer, & Loehlin, 1990; Thomas & Chess, 1977). Relatively undisputed is the hypothesis that the extraversion–introversion dimensional trait is reflective of a prominent temperament. Emotionality and activity levels have also received strong support as temperaments.

According to Rutter's theory, this limited number of temperaments helps to form what comes to be recognized as the individual's unique personality, although the personality is much broader than a simple collection of temperamental traits. Furthermore, Rutter proposes that as the individual interacts with family and society, these temperamental features may become reinforced by the social environment, thus producing the long-standing, enduring patterns of behavior that are characteristic of adult personalities. However, when particular temperamental features appear in the extreme or provoke unusual responses from the individual's environment, then PDs may result. The temperamental basis of a PD, along with its reinforcement history, therefore accounts for its enduring and inflexible nature.

Rutter's theory is confined to speculations about early childhood through adulthood, but there is little mention of issues related to later adulthood and the aged. Nevertheless, his theory can be used to generate a few hypotheses. Rutter argued that several longitudinal studies have shown "heterotypic" continuity, meaning that the phenotypic quality of the behavior changes over time while individual differences remain stable. Thus, early childhood passivity is predictive of noncompetitiveness in later adult life (Kagan & Moss, 1962). With respect to PDs, therefore, it is possible that the elderly should perhaps be evaluated according to different criteria or, at the least, the PD criteria should be examined for changes as a function of middle and later adulthood.

7.12.2.2 A Cognitive Theory of Personality Disorders

Pretzer and Beck (1996) have described difficulties in the psychotherapeutic treatment of patients with PDs, and they argue that even cognitive–behavioral treatments may prove counterproductive or ineffective if the therapist fails to recognize the specific nature of the PD and fails to modify treatment accordingly. In terms of the etiology of PDs from a cognitive perspective it is assumed that PDs develop phenomenologically, that is, through the person's view of their world. Thus, an individuals' perception of stimuli interacts with their prior beliefs and assumptions. An individual may react consciously and logically resulting in the observed emotional and behavioral responses to the perceived stimuli. However, prior misbeliefs (delusions) and false assumptions about the world may lead to inappropriate or maladaptive emotional responses and behavior. An individual may also commit "systematic errors in reasoning" which Pretzer and Beck labeled "cognitive distortions" that also result in inappropriate and maladaptive responses. They noted the prominence of at least 12 common cognitive distortions, such as viewing events in terms of mutually exclusive categories (dichotomous thinking) or focusing on one aspect of a complex situation to the exclusion of others (selective abstraction).

According to the theory, individuals are also likely to respond unconsciously or automatically to perceived stimuli. These ways of acting may have once been adaptive in an evolutionary sense. Beck (1992) has termed them "primeval strategies," and further, Pretzer and Beck (1996) have proposed that "human social change has outstripped physiological evolution [such that] we may well have also retained some biases in information processing that now tend to be maladaptive" (pp. 44–45). Thus, they argue that our inherited predispositions poorly fit some of the demands of modern society. For example, an earlier adaptive primeval strategy of predatory behavior may lead to the development of the antisocial PD, the earlier help-eliciting behavior may now result in the dependent PD, and earlier competitive behavior may now result in the narcissistic PD.

Nevertheless, Pretzer and Beck (1996) have argued that PD phenomena can be understood and treated without regard to inherited or inborn defects, and that inherited predispositions towards the development of PDs has not been clearly established. Moreover, their contribution appears neither simple nor straightforward. Overall, cognitive theory tends to emphasize that interactions between predispositions, the environment, and significant life events shape development rather than predispositions alone, and it is not external events that shape the personality but an individuals perception of those events that forms an individual's thinking and consequent behavior.

Although Pretzer and Beck's cognitive theory has a developmental perspective, it emphasizes early childhood influences upon the adult personality. Even though they hypothesize that traumatic experiences, either singular or recurrent, may alter an individual's personality over time, they do not address the influence of traumatic experiences upon the later adult personality. In fact, it could be easily hypothesized that 80 years of traumatic experiences should far outweigh a singular early traumatic experience. However, dramatic adult personality change is highly unlikely except for clear physiological reasons (e.g., brain disease, toxins, etc.). Thus, this aspect of their theory neglects personality issues of middle and late adulthood.

7.12.2.3 An Evolutionary Theory of Personality Disorders

Millon and Davis (1996) have proposed a highly complex and sophisticated evolutionary theory of PDs that attempts to link both normal and abnormal behavior to both phylogenetic and ontogenetic processes. Their theory explains why early experiences play a more profound role in the development of the personality than later experiences, drawing upon diverse sources of evidence such as Freud's writings about the influence of early childhood on the later adult personality and upon ethologists' observations of critical imprinting periods in maturational development.

Central to Millon and Davis' evolutionary theory are the hypotheses that four evolutionarily based "bipolarities" interact with four stages of early neuropsychological development to produce stable and consistent patterns of behavior that can either be adaptive or maladaptive. These bipolarities are pain–pleasure, active–passive, self–other, and thinking–feeling. The four bipolarities also reflect the parallel evolutionary processes of existence, adaptation, replication, and abstraction, respectively. The four parallel neuropsychological stages are sensory–attachment, sensorimotor–autonomy, pubertal–gender identity, and intracortical–initiative, respectively. Although their theory is comprehensive and far-reaching, they do not address PD issues of the elderly. Nor, despite the magnitude of their theory, does it offer much heuristically for the differential waxing or waning of PDs in the elderly.

7.12.2.4 Cloninger's Biosocial Theory and Personality Disorders

Cloninger (1987) has proposed a biosocial theory which asserts that phenotypic personality traits are the product of the interaction of genetically determined brain systems and environmental influences. He offered an operationalization of his theory in the TCI (Cloninger et al., 1994). This comprises seven major dimensions. There are four, purportedly genetically independent, trait dimensions: novelty seeking, harm avoidance, reward dependence, and persistence. The first three dimensions form the physiological component of the biosocial theory, and are identified with three primary monamine neurotransmitters: dopamine, serotonin, and norepinephrine. The first three traits are linked with these three neurotransmitters, respectively. Cloninger hypothesized that these three form neural temperaments which serve as discrete systems for the activation, inhibition, and maintenance of behavior in response to novelty, danger, and reward. The fourth character dimension, persistence, was not thought to be associated with a specific neurotransmitter. The decision to classify it as an autonomous factor in the model was based upon empirical statistical factor analyses.

The TCI also assesses three character dimensions: self-directedness, cooperativeness, and self-transcendence. These dimensions became later additions to the TCI to account for behavior not otherwise described by the initial three physiological dimensions and in order to determine whether a PD was present or not. The four temperament dimensions were designed to delineate clinical subtypes of personality but it appeared that they did not discriminate those individuals with PDs from those without PDs.

Another interesting feature of Cloninger's theory is that it attempts to link two primary components of human memory, procedural and declarative, to the formation of the seven trait and character dimensions. His theory postulates that the development of the four trait dimensions involves preconceptual responses to perceptual stimuli. Learned behavior patterns require the stimulus input of perceptual experience, but do not require conscious recall to replicate the behavior, which is the definition of procedural memory. The declarative memory system processes experience that is represented as words, images, or symbols. Once encoded, concept-based memories can be consciously retrieved, declared verbally, and willfully acted upon. Cloninger hypothesized that his three character dimensions reflected, in behaviorally expressed form, the information processed by the declarative memory system.

To account for PDs, Cloninger proposed that particular combinations of trait dimensions were predictive of various PDs. For example, he thought that the combination of high novelty seeking (high dopamine), low harm avoidance (low serotonin), and high reward dependence (high norepinephrine) was indicative of the histrionic PD, while the antisocial PD would be high on novelty seeking, and low on both harm avoidance and reward dependence. Presumably, all of the PDs would be low on the three character dimensions of self-directedness, cooperativeness, and selftranscendence.

Because the TCI is a relatively new test, there is a current lack of empirical evidence in support of Cloninger's biosocial theory. However, the previous version of the TCI (with only three trait dimensions) did receive modest but not overwhelming support in a few studies (e.g., Pfohl, Black, Noyes, Kelly, & Blum, 1990; Ruegg et al., 1993). Coolidge and Griego's (1996) study of the TCI with a new PD test (Coolidge Axis II Inventory; Coolidge & Merwin, 1992) provided moderate support for Cloninger's theory in a sample of 164 college students.

To date, Cloninger's biosocial theory makes no predictions about PDs as a function of the aging process. However, his biosocial theory is certainly fruitful for speculation. For example, there is substantial evidence (e.g., Morgan, May, & Finch, 1987) that there are normal age-related changes in the dopamine systems in humans and other mammals. There is an age-related, but not disease-related, loss in dopamine and its metabolites, a loss of dopaminergic neurons, and a decrease in particular types of dopamine receptors. Severe dopamine losses (greater than 75%) are characteristic of Parkinson's disease. Interestingly and anecdotally, these age-related losses of dopamine may, in part, account for the observation that some elderly persons do not typically engage in high novelty seeking behaviors. It appears that there are few or no age-related changes in the serotonin systems in humans. Although there appears to be a modest reduction in particular serotonin receptor sites, serotonin levels appear to be stable across the lifespan. Major serotonin level declines and serotonin receptor site losses are, however, indicative of Alzheimer's disease. Evidence regarding age-associated decreases in norepinephrine is scant.

In summary, it appears that Cloninger's biosocial theory is provocative and capable of generating a plethora of hypotheses concerning both pathological (PDs and brain syndromes) and nonpathological behaviors in the elderly. However, neurotransmitter systems in the brain are extremely complex and interactive, and it is doubtful whether singular descriptions of human behavior (e.g., novelty seeking) are based upon singular neurotransmitting systems. Furthermore, it is popularly suspected that many more neurotransmitters than have presently been discovered are yet to be discovered. Because of this, Cloninger's theory, at least in regard to PDs, may only be speciously complex and sophisticated.

7.12.2.5 Relevance of Personality Disorder Theories to the Elderly

It appears that many of the popular theories of PDs directly ignore issues related to aging and the elderly. Most of the theories, however, are useful in generating hypotheses about PDs in the elderly, regarding etiology, diagnosis, and treatment. For example, Rutter's hypothesis of heterotypic continuity in the lifespan is useful diagnostically, and it appears that comparisons of younger and older adults in terms of the *DSM* criteria for PDs may be useful. Pretzer and Beck's cognitive theory is provocative in that it appears to minimize the influences of traumatic experiences in the elderly. It appears that it would be fruitful to examine how, why, or if traumatic experiences vary from childhood to later adulthood. Also, it might be useful to determine whether and to what extent traumatic experiences differentially affect older people, that is, what characteristics do individuals possess that make them vulnerable or invulnerable to traumatic experience? Are there ways of inoculating the vulnerable? Are the elderly, as a group, more or less vulnerable? Also, Pretzer and Beck's primeval strategies are fascinating as a basis for the development of differences among the various PDs. Are there PDs unique to the elderly? If there are, do they have a primeval strategic basis?

Millon and Davis' evolutionary theory also does not address aging related issues. However, the four bipolarities (pain–pleasure, active–passive, self–other, and thinking–feeling) should be examined with respect to aging. Are there differences between younger and older persons? Also, evolutionary theories, in general, tend to ignore the latter end of the lifespan. After adaptation and replication, are humans simply devoid of evolutionary purpose? Do dramatic behaviors such as memory loss in the elderly have evolutionary meaning? What evolutionary purpose does personality stability possess?

Cloninger's biosocial theory can also be used to generate hypotheses about personality stability and change, and PDs in the elderly. To what extent do the chemical neurotransmitters in the brain affect behavior differentially in the elderly? How do declines in the neurotransmitter systems affect behavior in the elderly? Can classes of behaviors be directly linked to neurotransmitter systems in the elderly? If PDs are created by varying levels of neurotransmitters, can chemical interventions be developed to "cure" PDs?

This section on the etiology of PDs is far from an exhaustive review. However, a number of trends clearly emerge. The popular theories concerning PD attempt to integrate the biological and evolutionary factors with environmental influences. Most of these theories virtually, if not totally, ignore issues related to aging. It appears, however, that one can generate a host of provocative hypotheses from the theories with regard to aging issues, and psychologists should be encouraged to do so.

7.12.3 EPIDEMIOLOGY

Despite the growing body of literature about PDs in the elderly, there is a striking paucity of epidemiological and prevalence data for these interesting and challenging disorders in the older population. Moreover, reported rates for these conditions are far more inconsistent and controversial than estimates for more widely studied disorders, such as schizophrenia, cognitive impairment, or major depression. Such inconsistencies illustrate the difficulty clinicians and researchers have in accurately diagnosing PDs in the elderly.

Overall, surveys conducted in the 1980s show that prevalence rates for PDs in the older adult community range from as low as 2.8% to as high as 11% (Cohen, 1990). Prevalence figures are even more varied when mental health settings are considered. For example, Mezzich, Fabrega, Coffman, and Glavin (1987) conducted a retrospective chart review, and found that 5.1% of a sample of mixed inpatient and outpatient elders ($N = 494$) manifested PDs. Casey and Schrodt (1989) reviewed charts of 100 consecutive admissions to a geriatric psychiatry unit and found that 7% received a diagnosis of PD as determined by psychiatrist rating. In the largest retrospective study to date, Fogel and Westlake (1990) ascertained prevalence of characterological disorder in 2332 older inpatients suffering from major depression. Again, diagnoses were assigned by attending psychiatrists, with results showing a 15.8% PD rate. In a related study, Kunik et al. (1993) evaluated depressed elderly inpatients and found that 37 of 154 (24%) met criteria for a PD based on consensus diagnosis among psychiatrists. Similarly, Thompson, Gallagher, and Czirr (1988) showed that 33% of depressed elderly clients participating in a psychotherapy outcome study were diagnosed with a PD. More recently, Molinari and Marmion (1995) used a structured PD scale to assess PDs in elderly patients with mood disorders, revealing a 63% prevalence rate.

Limitations of many older epidemiological studies include their use of retrospective chart assessments, reliance on clinical judgment in assigning diagnoses, and the absence of reliability or validity checks of PD diagnoses. Although the National Institute of Mental Health Epidemiological Catchment Area programs were successful at providing quality epidemiological data for many common mental disorders, the PDs (with the exception of antisocial PD) were neglected in these surveys. Clearly, large-scale cross-sectional and longitudinal studies that employ standardized, objective, and validated diagnostic instruments, such as structured interviews, are warranted to fully investigate the prevalence of PD in the aged.

Other factors have also hampered epidemiological studies of PDs. For example, estimates of PDs have fluctuated greatly depending on the type of sample (e.g., general population, medical patients, psychiatric patients), method of diagnosis (e.g., clinician diagnosis, self-report personality inventory, structured interview), and type of research design (e.g., retrospective chart review, crosssectional, longitudinal). Furthermore, different diagnostic criteria have been employed in different studies, including research diagnostic criteria (Spitzer, Endicott, & Robins, 1978) and various versions of the *DSM* system. Spar and LaRue (1990) suggest that "Few data have been gathered on Axis II disorders in elderly patients, in part because most of the personality disorders in *DSM-III-R* have not been defined long enough for thorough studies to take place" (p. 180). Indeed, diagnostic systems prior to *DSM-III* did not provide well-operationalized or specific criteria for each particular PD, and reliability of diagnosis was notoriously poor. Since early investigations of PDs in the elderly utilized classification systems that are dissimilar from contemporary *DSM-III-R* and *DSM-IV* conceptualizations (Kroessler, 1990), meaningful comparison of prior and more current data is difficult. Despite gaps in the epidemiological research base, it can be concluded that PDs in the elderly are not uncommon, and that many clients so disordered are presently on the caseloads of diverse mental health practitioners.

Another epidemiological issue concerns differential rates for PDs among older males and females. According to the *DSM-IV*, borderline, dependent, and histrionic PDs are diagnosed more frequently in females, while antisocial and obsessive-compulsive PDs, and, to a lesser extent paranoid PD, are more common in males. However, it is unclear to what extent these differences apply to older individuals who typically were not adequately represented in the research studies from which conclusions about sex differences were drawn. Hard data are also lacking about the stability or change in PD symptoms as one enters old age. As noted earlier, *DSM-IV* describes a PD as a lifelong, stable pattern of thinking, feeling, and behaving. However, it also suggests that some disorders (e.g., antisocial and borderline) tend to remit with age, while others may exacerbate (e.g., obsessive-compulsive and schizotypal). However, these hypotheses should be empirically tested.

Tyrer (1988) investigated empirically the relationship between PD and increasing age and suggested that "mature" forms of PD such as obsessive-compulsive, paranoid, schizoid, and schizotypal remain stable with age, while more "immature" or flamboyant disorders such as antisocial, borderline, histrionic, and narcissistic are likely to decrease with age. This observation certainly has some anecdotal support, culled from clinicians with vast experience in the diagnosis and assessment of older persons. For some elderly clients, their current personality and social functioning appears markedly improved compared to the interpersonal chaos and occupational disaster characteristic of their earlier years. On the other hand, some older clients show exacerbation in their personality styles. In an interesting study, Coolidge, Burns, Nathan, and Mull (1992) examined these questions about course of PDs by directly comparing PD rates in younger and older subjects. Their results showed that the elderly were significantly more obsessive-compulsive and schizoid than their younger counterparts (based on mean T-scores), and were equal on avoidant and dependent PD scales. Although this cross-sectional study is intriguing, definitive research about the long-term course of individual PDs is lacking. Longitudinal studies will provide the clearest evidence about this issue, but these studies are obviously time-consuming, expensive, and difficult to carry out. However, information is sorely needed about this important conceptual and clinical issue if we are to better understand our elderly clients.

7.12.4 DIAGNOSIS

7.12.4.1 General Issues

The awareness and importance of PDs as a diagnostic category took a major leap in 1980 with the publication of *DSM-III*, with its innovative multiaxial diagnostic system. Clinical syndromes (located on Axis I) were separated from long-standing PDs (located on Axis II). Since that time, PD diagnosis has been fraught with controversy and difficulty, with the psychiatric community expressing grave (and justified) concerns about the apparent lack of reliability for these disorders. In general, the reliability of measurement refers to consistency, replicability, or stability. In the context of psychiatric diagnosis, reliability often refers to the extent of agreement between two raters concerning presence or absence of a psychiatric diagnosis. If different diagnosticians cannot agree about particular diagnoses, then those diagnostic categories are, at best, of limited value and, at worst, virtually meaningless. A full discussion of reliability issues and procedures is provided by Segal (1997) and Segal, Hersen, and Van Hasselt (1994). In fact, classic investigations of inter-rater reliability for diagnosis of *DSM-III* PDs produced results that were unacceptably poor (see Mellsop, Varghese, Joshua, & Hicks, 1982; Spitzer, Forman, & Nee, 1979). Moreover, these values were considerably lower than values for major axis I disorders, such as depression and schizophrenia.

The pervasive lack of agreement between clinicians and researchers when diagnosing PDs is particularly troublesome, given that reliability is a necessary, but insufficient, prerequisite for validity (Grove, 1987). Fortunately, there recently has been much improvement in this area with the publication of *DSM-III-R* and *DSM-IV*. In an effort to enhance reliability (and validity) of diagnosis, these classification systems have provided more specific and behaviorally-operationalized trait criteria for each particular PD. Following the development of better diagnostic criteria, several structured diagnostic interviews (discussed later) were created and refined; this further enhanced the ability to diagnose PDs consistently.

Whereas reliability refers to reproducibility and stability, the validity of psychiatric diagnosis refers to the extent to which a diagnosis actually measures what it purports to measure. The issue here is one of diagnostic accuracy and meaningfulness. Unfortunately, the validity of PD diagnosis is much harder to gauge and document accurately; thus, it represents a formidable challenge for clinicians and researchers alike. A common strategy employed is to compare PD diagnoses generated by a structured interview with diagnoses from another source, such as a clinical interview, chart review, or other testing procedure. However, such practice is far from ideal, mainly because these other diagnostic measures often suffer from questionable reliability and validity in the first place. Indeed, a major problem encountered by clinical researchers interested in the validity of PDs concerns the lack of a solid criterion diagnosis, a sort of "gold standard," against which to compare an interview generated diagnosis. This inadequacy severely restricts conclusions drawn from many validity studies.

The reader should be aware that the current *DSM-IV* Axis II system, while considerably better than its predecessors, is far from ideal. PD diagnoses generally are still less reliable than those of the major Axis I conditions, and most Axis II disorders show extensive overlapping, with individuals typically meeting criteria for several PDs at one point in time (Oldham et al., 1992). This extensive pattern of comorbidity and the fact that "pure" types are rarely encountered has fueled debate and discussion among clinical researchers as to the validity of categorical diagnosis of PDs in the first place (Frances, 1982; Oldham et al.). As cogently noted by Oldham et al. most studies

> have found that at least 50% of patients have two or more coexisting PDs. It may be that a dimensional approach is better suited for Axis II disorders than a categorical one that results in an unwieldy list of presumably comorbid diagnoses to describe "character pathology" in a given patient. (p. 213)

Usefulness of the three clusters (odd–eccentric, dramatic–erratic, anxious–fearful) proposed by the *DSM* system has also been criticized (e.g., Morey, 1988). Unquestionably, accurate diagnosis of PDs in any age group is still widely viewed as a complex and challenging task.

7.12.4.2 Personality Disorder Diagnosis and the Elderly

In the elderly population, diagnosis of PDs is complicated by several additional factors. First, diagnosis is affected by the longtime, widely held (albeit erroneous) belief that personality dysfunction either was not present or was not a significant mental health problem for older people. With this diagnostic mindset, PD symptoms may be minimized or overlooked altogether by the clinician. In fact, some researchers have suggested that diverse service providers to older individuals are biased against diagnosing PDs or defining problems as characterological (Kroessler, 1990; Rose, Soares, & Joseph, 1993; Rosowsky & Gurian, 1992). According to Rose et al. (1993) the chronicity, rigidity, and resistance to intervention attributed to individuals carrying a PD diagnosis often make the client seem "hopeless" and service providers feel "helpless." Professionals may lack appropriate knowledge about the manifestations of PDs in older adults, and consequently may fail to address this component in their assessment procedures.

Second, misdiagnoses often occur because individuals with PDs often present clinically with comorbid symptoms of major axis I disorders, most notably depression and anxiety, which are more easily recognized by both clients and service providers. Typically, clients view such acute symptoms as distressing, while lacking insight into their maladaptive personality style. In some cases, the blatant psychiatric symptoms may be consequences of the chronic interpersonal and occupational difficulties experienced by those suffering from dysfunctional personalities, but this cause–effect relationship is difficult to evaluate. Moreover, many clinicians simply are more experienced with the diagnosis and treatment of major mental illnesses, not PDs.

A third obstacle to the accurate diagnosis of PDs in older adults is that some signs of personality disturbance (e.g., avoidance, dependency, social withdrawal, odd thinking, irritability, eccentric behavior, or emotional lability) are wrongly perceived by some young and old individuals as "normal" in the aged population, or they are dismissed as being attributed to "old age." Such faulty assumptions almost certainly preclude appropriate assessment and diagnosis.

A fourth impediment to diagnosis is that *DSM-IV* criteria for some PDs have limited relevance or applicability to aged clients given their unique physical, cognitive, and social circumstances. Just as somatic problems may confound diagnosis of Axis I disorders in older individuals (e.g., depression, or panic disorder), Kroessler (1990) notes similar difficulties with the diagnosis of PDs in the aged. For example, he points out that many symptoms of a dysfunctional personality (e.g., aggressiveness, impulsiveness, brawling, child-beating, recklessness, and promiscuity) require physical activity. These criteria may not be applicable to some older adults for purely biological reasons in terms of the expected declines in energy, strength, and mobility due to normal aging. Despite this, however, such symptoms do appear in some elderly persons. For borderline PD in particular, many classic symptoms of this condition in younger persons (e.g., impulsive acting-out, sexual promiscuity, self-mutilating behaviors, and substance abuse) are likely to decrease in intensity with increasing age and physical/social limitations, although the underlying psychodynamics remain present (Fogel & Westlake, 1990; Rosowsky & Gurian, 1991, 1992). Reflecting on the fact that older clients meet fewer criteria for borderline PD than they did as younger clients, Rosowsky and Gurian (1991) propose that this difference may actually be due to inadequate criteria for the elderly rather than the lack of the disorder. We suggest that these "age-biases" in diagnostic criteria also apply to other personality types. Alternatively, some symptoms of apparent personality dysfunction in older individuals may actually be due to age-related social and biological factors, rather than a disordered personality. For example: social withdrawal (characteristic of schizoid and avoidant PD) may increase due to physical disabilities and transportation problems experienced by some elderly people; perceptions of exploitation by others (characteristic of paranoid PD) may be attributable to realistic concerns about crimes and scams directed at the elderly; and impulsivity, emotional lability, poor social judgment, and uncontrollable rage (characteristic of borderline and histrionic PDs) may actually be due to frontal lobe damage caused by vascular accidents in some older persons.

Fifth, a major requirement for the diagnosis of any PD is the experience of clinically significant distress or impairment in social or occupational functioning (*DSM-IV*, criterion C). However, as individuals age, they work less frequently and have smaller social networks due to sensory and physical disabilities, as well as the cumulative loss of family and friends through death or relocation. Thus, the requirement of social/occupational impairment may preclude accurate PD diagnosis in older adults whose social world and work opportunities are much different from their younger counterparts upon whom many taxonomies are based. As age-related behavior changes may either mimic or mask PD symptoms we concur with Kroessler (1990) and also argue for inclusion of age-associated criteria in the diagnostic guidelines.

Several case reports have appeared in the literature documenting the unique diagnostic and intervention challenges faced by mental health professionals. Specifically, a vivid case description has been reported for borderline PD (Siegel & Small, 1986). More recently, case examples of antisocial (Howard, Bandyopadhyay, & Cook, 1992), histrionic, borderline, and avoidant PDs (Rose et al., 1993) in old age have been presented. It is obvious, however, that systematic research is necessary to clarify clinical manifestations and develop clearer profiles of each PD in the aged. As noted previously, longitudinal studies following personality-disordered individuals into later life are needed to assess changes over time in symptom patterns and personality characteristics of older individuals. It is probable that some symptoms are robust, some appear in muted format in the aged, and some are irrelevant. Given the diagnostic problems highlighted in this account, the need for elder-specific diagnostic criteria is underscored. For example, the number needed to assign a diagnosis (e.g., five out of eight for histrionic PD) may be modified (usually lowered) to improve diagnostic accuracy and application to the elderly. This issue can be determined empirically by validity studies assessing cut-off rates as the criteria requirements are adjusted. When evaluating and diagnosing PDs in the elderly, clinicians are also encouraged to recognize and be sensitive to potential age-biases in the *DSM-IV* system. In conclusion, a significant ramification of these diagnostic difficulties is that determination of the most appropriate form of intervention is often obfuscated. Treatment is often not indicated if the behavior is considered a "normal" concomitant of the aging process; or, when intervention is applied, it solely targets the blatant anxiety or depressive symptoms, while the etiologically significant underlying personality dysfunction is minimized, or even worse, completely ignored.

7.12.5 ASSESSMENT

Accurate assessment of PDs is a critical component of patient care given the fact that most clinicians working with older individuals will have some clients with PDs on their caseload. As diagnostic criteria for PDs has become more refined in recent years, the assessment of PDs has also flourished. Several instruments are available to the clinician, and these can be divided into two broad categories: self-report inventories and structured clinical interviews. Both assessment approaches are widely applied in clinical and research contexts, and both have their own advantages and disadvantages. On the one hand, structured interviews generally are more reliable and allow consideration of important observational data, but they require extensive training and experience on the part of the interviewer, and can be lengthy to conduct especially with severely disordered clients. On the other hand, self-report personality inventories are easy to administer and take less time, but in some cases tend to overpathologize and are prone to deviant test-taking response behaviors. This chapter now focuses on the description and development of several popular self-report inventories and structured interviews, as well as the application of these devices to older adults.

7.12.5.1 Self-report Personality Inventories

Instruments to be reviewed in this chapter include the *Millon Clinical Multiaxial Inventory-III (MCMI-III*; Millon, 1994), the *Personality Diagnostic Questionnaire-4 (PDQ-4*; Hyler, 1994), and the *Coolidge Axis II Inventory (CATI*; Coolidge, 1984; Coolidge & Merwin, 1992). These instruments are among the most commonly utilized tools for measuring *DSM-IV* PDs. Other self-report instruments have been developed to measure PDs, including the Wisconsin Personality Disorders Inventory (Klein et al., 1993). Also, Morey, Waugh, and

Blashfield (1985) have derived PD scales from the original Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1983). The MMPI, and its revision, the MMPI-II (Hathaway & McKinley, 1989), are not true measures of *DSM*-based PDs. Rather, they evaluate personality traits, symptom profiles, and axis I disorders. A full review of all measures is beyond the scope of this chapter. Therefore, we will restrict our reviews to *MCMI-III, PDQ-4,* and *CATI.*

7.12.5.1.1 Millon Clinical Multiaxial Inventory-III

The original *MCMI* (Millon, 1983) has undergone two revisions, that is, *MCMI-II* (Millon, 1987) and *MCMI-III* (Millon, 1994). *MCMI-III* is a 175-item, true-false, self-report inventory specifically designed to assess PDs. This instrument is widely used in research and clinical activities, and its taxonomy is "aligned" with *DSM-IV*. The *MCMI-III* includes 14 personality pattern scales (Axis-II related) including: schizoid, avoidant, depressive, dependent, histrionic, narcissistic, antisocial, aggressive (sadistic), compulsive, passive–aggressive (negativistic), self-defeating, schizotypal, borderline, and paranoid. Additionally, 10 symptom scales (Axis-I related) are provided, covering moderate clinical presentations (e.g., anxiety, dysthymia, alcohol dependence) and severe symptoms (e.g., thought disorder, major depression). It has three validity scales designed to detect random or confused response patterns and defensiveness. The *MCMI* is designed to be given only to those suspected of having a PD, and thus, should not be used for differential diagnosis in nonclinical populations. The *MCMI* has been the focus of numerous publications since its development in 1967, and earlier versions have been shown to have good psychometric properties, although it is said to be more reliable in diagnosing among PDs than in differentiating between clinical syndromes (Millon, 1992). Psychometric properties of the *MCMI-III* are currently being evaluated.

7.12.5.1.2 Personality Diagnostic Questionnaire-4

The original *PDQ* was revamped to match changes in the *DSM-III-R* system, and was renamed the *PDQ-R* (Hyler & Rieder, 1987). A newer version of *PDQ-R* has been created (*PDQ-4*; Hyler, 1994) and this is now consistent with *DSM-IV*. The *PDQ-4* assesses the 10 standard PDs in the *DSM-IV*. It contains 85 self-report, true-false items and takes about 30 minutes to complete. It has two validity scales: one detects underreporting of psychopathology and the other identifies those who are responding randomly or inconsistently. A supplementary clinical significance scale was designed for *PDQ-4*; to control for an excess of false positives. Also, a summed "total" score of all pathological items representing an overall level of personality dysfunction can be generated. Interestingly, an ancillary version, *PDQ-4+*, can be used to evaluate passive–aggressive and depressive PDs as listed in the appendix of *DSM-IV*. A computer-assisted version is available for administration and scoring. The *PDQ-R* has been demonstrated to be an efficient instrument for screening personality disorders according to *DSM-III-R* (Hyler, Skodol, Kellman, Oldham, & Rosnick, 1990; Hyler, Skodol, Oldham, Kellman, & Doidge, 1992), and has been found to have high sensitivity and moderate specificity for most axis II disorders (Hyler et al., 1990; Hyler et al., 1992). Most recently, Trull and Larson (1994) have conducted a validity study of the *PDQ-R*, comparing it to a structured clinical interview. They concluded that the *PDQ-R* was overly sensitive to psychopathology (false positives), although it was suggested that the *PDQ-R* might be helpful in ruling out PDs. The new clinical significance scale of the *PDQ-4* may help in this regard.

7.12.5.1.3 Coolidge Axis II Inventory

The *CATI* (Coolidge, 1984; Coolidge & Merwin, 1992) is a 225-item, self-report and significant-other report inventory developed and revised to assess PDs according to the diagnostic criteria of *DSM-IV*. The inventory currently contains 14 PD scales, retaining the *DSM-III-R* sadistic and self-defeating PDs, and offering the new *DSM-IV* depressive PD. The items on each PD scale were designed to cover all of the criteria listed in *DSM-IV* (or *DSM-III-R*). The *CATI* also provides assessment for 13 Axis I scales including depression, anxiety, schizophrenia, and post-traumatic stress disorder. The new *DSM-IV,* Personality Change Due to a General Medical Condition is also evaluated, with scores provided for each of the five subtypes: apathy, disinhibition, emotional lability, aggression, and paranoia. One unique feature of *CATI* is that it has an 18 item neuropsychological dysfunction scale for assessing symptoms of brain disease, trauma, and dysfunction, with three subscales assessing language dysfunction, memory and concentration difficulties, and somatic complaints related to brain dysfunction. The *CATI* also includes a 16 item executive functions scale with three subscales measuring poor planning, decision-making difficulty, and task incompletion. The test–retest reliability (one week intervening) for the *CATI* is good (mean r = 0.90; range = 0.78–0.97), and internal consistency is moderate (median r = 0.76; range = 0.66–0.87). With regard to validity, a 50% concordance rate with clinicians' diagnoses (based on *DSM-III-R* criteria) for 24 personality-disordered patients was found, and the *CATI* showed moderate concurrent validity with the *MCMI-II* (median r = 0.58; range = 0.10–0.87) with the same patients (Coolidge & Merwin, 1992).

7.12.5.1.4 Application to older adults

Application of the *MCMI* to older psychiatrically impaired adults has been explored in only one study. Hyer and Harrison (1986) administered the inventory to 60 elderly psychiatric inpatients. Results showed that rates of dependent and avoidant PDs were highest in this older group, a finding that mirrors results from younger age groups. In contrast, histrionic, narcissistic, and antisocial PDs had the lowest rates. These disorders were characterized as higher intensity personality styles. Notably, Hyer and Harrison suggested that these high energy personality types tend to become less prominent with increasing age.

Literature regarding the *CATI* and older adults is also limited. Coolidge and colleagues (1992) administered the *CATI* to normal younger (N = 573; mean age 24.0 years) and older (N = 36; mean age 69.4 years) individuals and compared results. They found that, for Axis I syndromes, older adults were significantly less anxious, but reported more signs of brain dysfunction. No group differences were reported on the depression scale. As for Axis II, the elderly scored significantly lower on antisocial, borderline, histrionic, narcissistic, paranoid, passive–aggressive, schizotypal, sadistic, and self-defeating scales than their younger counterparts. By contrast, the older adult sample was significantly more obsessive–compulsive and schizoid. No group differences were obtained for avoidant or dependent PD scales. Coolidge and colleagues (1992) noted that, in general, the older sample scored low on questions associated with impulsivity and endorsed items consistent with restricted emotional expressiveness. In this study, age differences on the *CATI* were assessed in nonclinical, normal subjects. To date, age comparisons have not been examined in psychiatric populations. We found no studies of the *PDQ* with older persons.

The dearth of studies applying the *PDQ, MCMI*, and *CATI* to older populations represents a major gap in the research literature. Recently, however, the concurrent validity of the *MCMI-II* and *CATI* has been evaluated in a pilot study (Silberman, Roth, Segal, & Burns, in press) targeting chronically mentally ill elderly inpatients (N = 30; mean age 63.3 years). Patients were diagnosed by a psychiatrist as having a chronic mental illness (e.g., schizophrenia, bipolar disorder). The *MCMI-II* and *CATI* were concurrently administered in counterbalanced fashion and the data submitted to correlational analyses. The median correlation coefficient (raw score sums for the *CATI* and *MCMI-II*) for the 13 PD scales was 0.55 (range - 0.13 for schizoid to 0.88 for borderline), which was similar to the moderate results obtained by Coolidge and Merwin (1992) with a younger and less severe sample (24 psychiatric outpatients, mean age 38.0 years).

7.12.5.2 Structured Clinical Interviews

Since the 1960s, several structured diagnostic interviews have been developed for clinical, research, and training applications. Notably, structured interviews have been devised to assist in diagnosis of all standard Axis II PDs and all major Axis I clinical syndromes. Prominent interviews for Axis I conditions include the Schedule for Affective Disorders and Schizophrenia (Endicott & Spitzer, 1978), the *Diagnostic Interview Schedule* (original *DIS*; Robins, Helzer, Croughan, & Ratcliff, 1981; *DIS-IV*; Robins, Cottler, Bucholz, & Compton, 1996), and the Structured Clinical Interview for *DSM-IV* (First, Spitzer, Gibbon, & Williams, 1995a). (See recent review by Segal & Falk [in press] for further description of interviews for Axis I disorders.) Principal interviews for Axis II PDs include the Structured Interview for *DSM-IV* Personality (SIDP-IV), the International Personality Disorder Examination (IPDE), and the Structured Clinical Interview for *DSM-IV* Axis II Personality Disorders (SCID-II). Each PD interview is closely aligned to the *DSM* system, and subsequently has been revamped to match refinements in that classification scheme as it has evolved. Overall, structured interviews for PDs have improved clinical and research endeavors by providing a more standardized, scientific, and quantitative approach to the evaluation of these disorders. Indeed, these instruments have strongly contributed to the advancement in diagnostic clarity and precision for PDs. For each instrument, the purpose and construction will be briefly discussed, followed by some thoughts about the clinical applications of these instruments with older adults. PDs covered by the *DSM-IV* version of each instrument are presented in Table 1.

Table 1 *DSM-IV* personality disorders diagnoses covered by the SCID-II, IPDE, and SIDP-IV.

	Structured interview		
Personality disorders	*SCID-II*	*IPDE*	*SIDP-IV*
Cluster A			
Paranoid	X	X	X
Schizoid	X	X	X
Schizotypal	X	X	X
Cluster B			
Antisocial	X	X	X
Borderline	X	X	X
Histrionic	X	X	X
Narcissistic	X	X	X
Cluster C			
Avoidant	X	X	X
Dependent	X	X	X
Obsessive-compulsive	X	X	X
Other personality disorders			
Mixed or PD NOS	X	X	X
Sadistic	no	no	no
Self-defeating	no	no	X
Depressive	X	no	X
Negativistic	X	no	X

7.12.5.2.1 ***Structured Interview for*** **DSM-IV** ***Personality***

The SIDP-IV (Pfohl, Blum, & Zimmerman, 1995) is a comprehensive, semistructured diagnostic interview for *DSM-IV* PDs. The SIDP-IV covers 14 axis II diagnoses, including the 10 standard PDs, mixed PD, as well as self-defeating, depressive, and negativistic PDs which are proposed for "further study" in *DSM-IV*. The current edition of this popular instrument (SIDP-IV) has its roots in earlier versions that date back over a decade ago. In fact, the original Structured Interview for *DSM-III* Personality Disorders (SIDP; Stangl, Pfohl, Zimmerman, Bowers, & Corenthal, 1985) was the first structured interview designed to diagnose the full range of *DSM-III* PDs. Soon after, the Structured Interview for *DSM-III-R* Personality Disorders (SIDP-R; Pfohl, Blum, Zimmerman, & Stangl, 1989) was published to match changes in *DSM-III-R*.

Prior to the SIDP-IV structured interview, a full evaluation of current mental state or axis I conditions is required (Pfohl et al., 1995). This is not surprising given that self-report of enduring personality characteristics can be seriously compromised in a respondent experiencing acute distress. Indeed, the aim of all personality assessment measures is to rate the respondents typical, habitual, and lifelong personal functioning rather than acute or temporary states. For the most part, each SIDP-IV question corresponds to a unique *DSM-IV* axis II criterion. To help guide the interviewer, the specific *DSM* criterion associated with each question is provided on the form for easy reference. Items are not presented in a disorder-by-disorder fashion; rather, items are grouped according to 10 "topical sections" that reflect different dimension of personality functioning. Examples of these groupings include: interests and activities, close relationships, emotions, self-perception, and social conformity (Pfohl et al.). Questions typically are open-ended to encourage respondents to talk about their *usual* behaviors and long-term functioning. Based on patient responses, each criterion is rated on a scale with four anchor points, ranging from not present to strongly present and debilitating. The SIDP-IV requires that a trait be prominent for most of the last five years to be considered a part of the respondents' personality. This "five year rule" helps ensure that the particular personality characteristic is "stable and of long duration" as required by the "general diagnostic criteria" for a personality disorder described in *DSM-IV*.

Like the IPDE and SCID-II, significant clinical judgment is required to properly administer the SIDP-IV as interviewers are expected to ask additional questions to clarify patient responses when necessary. Also data are not limited to self-report; rather, chart records, and significant others such as relatives and friends who know the patient well should be consulted when available. Such collateral information is particularly prized when evaluating personality disordered individuals, who tend to lack insight into their own maladaptive personality traits and distort facts about their strengths and limitations. Moreover, informants can also provide diagnostic data that can help resolve the state/trait distinction about specific criterion behaviors. Overall, the SIDP typically requires 60 to 90 minutes for the patient interview, 20 minutes for interview of significant informants, and approximately 20 minutes to tabulate the responses and make diagnostic conclusions.

Reliability (inter-rater and internal consistency) of SIDP diagnoses has been evaluated in many studies (e.g., Stangl et al., 1985; Nazikian, Rudd, Edwards, & Jackson, 1990; Hogg, Jackson, Rudd, & Edwards, 1990; Jackson, Gazis, Rudd, & Edwards, 1991) with generally favorable results. Convergent validity has been assessed in several investigations in which SIDP diagnoses were compared to diagnoses from self-report Axis II instruments, such as the *MCMI*, and results typically have been modest at best (Hogg et al., 1990; Jackson et al., 1991; Miller, Streiner, & Parkinson, 1992; Nazikian et al., 1990; Turley, Bates, Edwards, & Jackson, 1992). It should be noted, however, that these studies may not be a fair test of the validity of the SIDP due to the differing assessment methods (interview vs. self-report) and the questionable validity of self-report PD measures.

7.12.5.2.2 International Personality Disorder Examination

The IPDE (Loranger et al., 1994) is an extensive, semistructured diagnostic interview for PDs. Although the 1994 version is compatible with the *DSM-III-R* and *ICD-10*, a version aligned with *DSM-IV* criteria has been produced by the World Health Organization (WHO; in press). The IPDE is an outgrowth of the Personality Disorder Examination (PDE) which was developed and refined over a five year period from 1983 to 1988 (Loranger, Hirschfeld, Sartorius, & Regier, 1991). Impetus for the development of the IPDE came from WHO and the US Alcohol, Drug Abuse, and Mental Health Administration (ADAMHA) in their joint effort aimed at producing standardized assessment instruments to measure mental disorders on an worldwide basis. The IPDE was selected by the WHO/ADAMHA for use as an instrument capable of assessing PDs in different languages, cultures, and countries. As such, the IPDE allows for diagnosis of PDs according to both the *DSM-IV* and *ICD-10* systems.

Items reflecting PD criteria according to the *DSM* and *ICD* are grouped into six thematic headings: work, self, interpersonal relationships, affects, reality testing, and impulse control (Loranger et al., 1991). Like the SIDP-IV, disorders are not covered on a one-by-one basis. IPDE sections typically begin with open-ended prompts to encourage respondents to elaborate about themselves in a less structured fashion. Then, specific questions are asked to evaluate each *DSM* and *ICD* criterion. There are separate modules for the *DSM-IV* and *ICD-10* classification systems. This division serves to reduce administration time, as interviewers typically follow one system or the other. Still, the IPDE typically requires 3–4 hours.

The IPDE requires that a trait be prominent during the last five years to be considered a part of the respondent's personality. Information about age of onset of particular behaviors is also explored to determine if a late-onset diagnosis is appropriate. When a respondent acknowledges a particular trait, interviewers follow-up by asking for examples and anecdotes to clarify the trait or behavior, gauge impact of the trait on the person's functioning, and fully substantiate the rating. Such probing requires significant clinical judgment and knowledge about each criterion on the part of interviewers. Moreover, some items are rated based on observation of the respondents behavior during the session, and this too requires a certain level of clinical expertise. To supplement self-report, interview of informants is encouraged. All items are rated on a three-point scale with the following definitions: "O" indicates that the behavior or trait is denied or within normal limits, "1" refers to present to an accentuated degree, and "2" signifies pathological/meets criterion (Loranger et al., 1994). The final output of the IPDE is extensive, including presence or absence of each criterion, number of criteria met for each disorder, a dimensional score (sum of individual scores for each criteria for each disorder), and a categorical diagnosis (definite, probable, or negative) (Loranger et al., 1994).

Like the SIDP-IV, inter-rater reliability of the IPDE (or PDE) generally is good, from report to report (Loranger et al., 1994; Loranger, Susman, Oldham, & Russakoff, 1987; Standage & Ladha, 1988). Not surprisingly, convergent validity coefficients typically have been weaker, ranging from 0.14 to 0.66 (Skodol, Oldham, Rosnick, Kellman, & Hyler, 1991; also see Hunt & Andrews, 1992; Pilkonis, Heape, Ruddy, & Serrao, 1991; Soldz, Budman, Demby, & Merry, 1993).

7.12.5.2.3 Structured Clinical Interview for DSM-IV *Axis II Personality Disorders*

To complement the Axis I version of the SCID, Spitzer and colleagues endeavored to develop a semistructured interview that would facilitate improved diagnosis of Axis II PDs. Their efforts resulted in publication of the SCID-II (version 1.0; Spitzer, Williams, Gibbon, & First, 1990), which targeted 11 PDs according to the then current *DSM-III-R* system. In 1994, the SCID-II was updated (SCID-II, version 2.0; First, Spitzer, Gibbon, Williams, & Benjamin, 1994) so that questions correspond to the new diagnostic criteria in *DSM-IV*. In this *DSM-IV* version, the 10 standard PDs are evaluated, along with the proposed depressive and negativistic PDs, while self-defeating and sadistic PDs have been deleted.

The SCID-II is usually employed in conjunction with the SCID-I, which typically is administered prior to personality assessment. This is encouraged so that the respondents present psychological state can be considered when judging accuracy of self-reported personality traits (First, Spitzer, Gibbon, & Williams, 1995b). A unique feature of the SCID-II is that it includes a 117 item, self-report, forced choice, yes/no screening component (called the Personality Questionnaire) that is completed prior to the interview portion and requires about 20 minutes to complete. The purpose of this screening measure is to reduce overall administration time. In the questionnaire, initial diagnostic items for each PD are presented, so that later sections of the structured assessment can be omitted if particular personality traits are denied.

During the structured interview component, only positively endorsed screening responses are further pursued to ascertain whether the symptom criteria is actually at clinically significant levels. Each SCID-II question taps a unique PD criterion, and the actual *DSM-IV* diagnostic criteria are printed on the interview page for easy review. Responses are coded on a three-point system (i.e., 1 = absent, 2 = subthreshold, 3 = threshold, ? = inadequate information). Each disorder is assessed completely and diagnoses are made before proceeding to the next disorder (First et al., 1995b). The modular format permits researchers and clinicians to tailor the SCID-II to their specific needs and reduce administration time. SCID-II administrators are expected to use their clinical judgment to clarify responses, gently challenge inconsistencies, and ask for additional information as required to accurately assess each disorder. Like the SIDP-IV and IPDE, collection of diagnostic information from ancillary sources is permitted. Complete administration of the SCID-II typically takes under 50 minutes (First et al., 1995b), which is substantially shorter than other structured measures. Training requirements and interviewer qualifications are similar to that of the other structured interviews for PDs.

With regard to psychometric properties of the SCID-II, an impressive large-scale multisite test–retest reliability project has recently been completed (First et al., 1995) with reasonably good results (overall weighted kappa = 0.53; range = 0.34–0.74). Other studies have reported even higher inter-rater reliability values for the SCID-II (Arntz et al.,1992; Brooks, Baltazar, McDowell, Munjack, & Bruns, 1991; Fogelson, Nuechterlein, Asarnow, Subotnik, & Talovic, 1991; Malow, West, Williams, & Sutker, 1989; O'Boyle & Self, 1990). Like the SIDP-IV and IPDE, less empirical attention has been devoted to validity of SCID-II diagnoses, and the studies that have been conducted generally produce only fair validity coefficients across different methodologies and criterion diagnoses used (O'Boyle & Self, 1990; Skodol et al., 1991; Skodol, Rosnick, Kellman, Oldham, & Hyler, 1988).

It is apparent that application of structured interviews for PDs over the last 15 years has greatly facilitated the task of psychiatric diagnosis for these conditions. Reliability values for the structured interviews generally indicate modest to excellent agreement with diverse patient populations and experimental designs. Most importantly, these values greatly surpass results from early investigations with unstructured interviews (Mellsop et al., 1982). Unfortunately, although reliability rates are now more acceptable for most PDs, it remains to firmly establish the validity. Most studies in this area have focused on basic reliability, differentiation of separate PDs from each other, and description of these conditions. Firm establishment of construct and predictive validity for the PDs is lacking in the literature. As such, investigation in this area should be the major focus of future research attention.

7.12.5.2.4 Application to older adults

As previously noted, each major structured interview has been subjected to extensive evaluation by clinical researchers. Unfortunately, the literature regarding specific application of these instruments with the elderly is sparse, although several clinical studies have been reported. For example, Abrams, Alexopoulos, and Young (1987) administered the

PDE to 21 older adults who had recovered from depression and 15 without a history of depression. The purpose of this study was to investigate the relationship between personality traits and late-life depression. Only two study participants met criteria for a PD and no reliability estimates were reported. In a more recent study also employing the PDE in a sample of 30 recovered depressed older adults, inter-rater reliability was high for all PDs, except histrionic (Abrams, Rosendahl, Card, & Alexopoulos, 1994). In a similar investigation, Schneider, Zemansky, Bender, and Sloane (1992) used the SCID-II to diagnose PDs in a group of older adults with history of major depression, although no reliability data were reported. Thompson et al. (1988) obtained Axis II formulations by using the SIDP in a sample of 79 depressed older adults, and found high inter-rater reliability. These clinical reports provide some evidence that the structured interviews can be successfully applied to older adults. However, larger reliability and validity studies are warranted especially with more diverse elder populations (e.g., medical patients, minorities, psychiatric inpatients).

Several additional concerns about the application of structured interviews with older adults should be noted. A common feature among all three structured interviews is that respondents are encouraged to describe their "typical or usual" functioning, rather than their often altered personality functioning during times of acute psychiatric illness. As such, during the course of the structured interview, respondents are sometimes asked to describe their behaviors at different points in time, possibly spanning several years. Unfortunately, such distinctions may be difficult for some elderly clients to make, as memory problems can preclude accurate self-report about behavior patterns many years ago. Another problem with the utilization of structured interviews with older clients is the considerable length of time required for completion. With young clients, administration time for the various interviews typically ranges from 1.5 to 3.5 hours. However, administration may take considerably longer with older persons. One reason for this is that older individuals simply have more extensive and complicated histories to review. Some older persons also require several "breaks" that may not be needed by younger individuals. Indeed, many older adults fatigue more quickly, and this must be monitored as responses will become less accurate if the client becomes inattentive or unmotivated. Older adults typically will perform their best when given frequent opportunities to stretch, take a brief walk, rest, or use the bathroom. Sometimes, it may be helpful to divide the structured interview into several shorter sessions.

Sensory impairments can also affect the evaluation. Older persons with hearing difficulties may misunderstand parts of the query or fail to answer the question entirely. It is often helpful to sit closer to the older client, face him or her directly, speak slowly and clearly, and reduce background noise in the evaluation room. The interested reader is referred to Edelstein, Staats, Kalish, and Northrop (1996) for full discussion of the effects of sensory deficits on the assessment of older adults. Finally, some older adults may respond negatively to the structure imposed by the interviews. In these cases, it is advisable to spend more time developing rapport, reflect more feelings during the interview, allow for more elaboration and venting from the client about troublesome symptoms, and explain the purpose and format of the structured interview. In all, flexibility and sensitivity are required when assessing and interviewing the personality-disordered older adult.

7.12.6 TREATMENT

The personality-disordered older adult is often ill-equipped to handle the challenges and changes associated with the normal aging process. A lifetime of social and occupational failures typically exacerbates the clinical picture, and increases the older adults sense of disappointment and hopelessness. As such, these individuals are often in need of counseling or supportive services to reduce their frustrations and difficulties. Unfortunately, little is currently known about the treatment of various PDs in the elderly. And, most of the literature is in the form of clinical case studies with a striking lack of group studies. Much of the literature we will discuss pertains to treatment models developed for younger individuals. The reader should be aware, however, that specific literature about treatment of PDs in the elderly is in short supply.

Evidence suggests that the majority of older adults with psychiatric problems do not seek or receive appropriate mental health services. Lazarus, Sadavoy, and Langsley (1991) have aptly described the many barriers to psychotherapy facing the current cohort of elderly persons: their attribution of psychiatric symptoms to physical rather than psychiatric causes, emphasis on medical treatment, stigmatization associated with psychiatric care, practical deterrents such as cost, transportation, and physical disabilities, and negative family and physician attitudes about geriatric mental health treatment. Unfamiliarity with current mental health treatment and a desire to remain independent also preclude intervention in some cases.

Two other factors specifically impede appropriate treatment of PDs in the elderly. The first concerns the lack of appropriate diagnosis. As we have discussed earlier, PDs are sometimes underdiagnosed by mental health professions due to their unfamiliarity with the disorders, the belief that PDs are rare in the elderly, an overemphasis on the Axis I symptoms that the client perceives as the problem, and a masking of Axis II diagnoses by the more flagrant or pressing Axis I symptoms. Although the underlying personality may not be taken into account, it certainly affects treatment outcome for these clients. Consider the treatment of an older male adult who is clinically depressed because he has recently retired and subsequently lost his wife to a fatal illness. Another elderly male may present with similar symptoms of depression, but his symptoms are not reflective of recent losses but rather are the effects of a lifetime of interpersonal chaos, self-destructive actions, and a poorly developed sense of self characteristic of borderline PD. Appropriate treatment for these two individuals most likely will take remarkably different forms. However, failure to recognize the moderating impact of personality dysfunction on psychiatric symptoms can result in poor treatment planning and therapeutic outcome. Indeed, in their classic report, Thompson et al. (1988) investigated whether presence of PDs affect outcome in treatment of 75 depressed older adults. They found that older adults with PDs did considerably worse in treatment than those without PDs, and these effects were still present at six month follow-up. Similar results have been reported in related studies with younger depressed clients with comorbid PD (Frank, Kupfer, & Jarret, 1987; Pilkonis & Frank, 1988).

The second factor hindering treatment of PD in older adults is that individuals (both older and younger) with a significant PD often fail to recognize their symptoms as signs of a psychiatric disturbance. In other words, they lack insight into the maladaptive nature of their behavior. Imagine an older adult suffering from narcissistic PD. This individual may have great difficulty maintaining adequate employment because of his sense of entitlement, condescending attitude, and difficulty following directions from his bosses whom the person regards as inferior. This older individual may blame his problems on his bosses who do not properly appreciate his talents or he may believe he is being discriminated against based on his age, when the real problem is the dysfunctional attitudes and behaviors characteristic of his personality type. Such individuals, who lack awareness of their own personality disturbance, typically see no need for personal change or psychiatric intervention. In general, individuals with a PD seek therapy when they begin to manifest troubling symptoms of an Axis I disorder, such as anxiety or depression. They see these symptoms as ego-dystonic and present at the clinician's office expecting relief. One tenet in treating older adults in this condition is to focus one's therapeutic attention initially on reduction of Axis I clinical symptoms until maximum therapeutic gain has been achieved (Abrams, 1991). At this early point, the therapeutic goal negotiated between therapist and client converge.

The early stage of treatment focusing on symptom relief is important for developing a therapeutic alliance and laying the foundation for later, more difficult, and more intensive treatment of the underlying character pathology. It is necessary to spend considerable time forming a therapeutic relationship with the older client. Indeed, a strong bond and safe environment is crucial to help older clients begin the process of viewing themselves and their behaviors more realistically (often more negatively). The older personality-disordered client may have few skills in this area and may have difficulty tolerating the negative feelings that often arise during this process. It is often helpful to proceed with caution and to be sensitive to increases in symptoms and distress. Typically, long-term psychotherapy is needed to address a lifetime of long-standing maladaptive behavior patterns. And, in some cases, treatment goals should be modest (Abrams, 1991).

Several models of treatment specific to PDs have appeared in the literature. For example, Young (1994) combines psychodynamic, object relations, and gestalt therapy concepts with standard cognitive therapy techniques in his schema-focused approach for treatment of PDs. Millon, one of the leaders in formulation and assessment of PDs, has developed a personologic and integrative treatment approach for PDs (Millon & Davis, in press), and Benjamin (1996) has presented her interpersonal approach to case conceptualization and treatment. These approaches have generated a great deal of anecdotal support, but little empirical validation has been reported. Other theorists have concentrated their attentions on one particular PD, with borderline PD receiving the most attention. For example, Paris (1994) describes a multidimensional treatment, while Horwitz et al. (1996) explicate a modified psychodynamic approach for borderlines. An innovative treatment for borderline PD, dialectical behavior therapy (DBT; Linehan, 1993) combines tenets from humanistic therapies and cognitive behavioral problem solving techniques. Several well-designed controlled outcome studies have been conducted to evaluate effectiveness of DBT with promising results (e.g., Linehan, Armstrong, Suarez, Allmon, & Heard, 1991; Linehan, Heard, & Armstrong, 1993), and DBT has recently been approved as an empirically validated treatment for borderline PD. The question remains whether this approach (as well as the others mentioned above) can be adapted for use with *older* individuals with severe personality dysfunction. In summary, although psychotherapy is generally considered the treatment of choice for PDs, few studies have actually tested various therapy models with older persons. The complexity of these disorders and well-established difficulty forming therapeutic relationships with personality-disordered individuals no doubt contribute to this lack of investigation.

Besides psychotherapeutic interventions, the psychopharmacological management of clients with PDs has been the focus of increasing attention in the past decade. Pharmacotherapy is sometimes used as an adjunctive strategy to ameliorate some acute depressive or anxiety symptoms and, in fact, can help some personality-disordered patients better engage in psychotherapy (Soloff, 1990). Such treatment is often welcomed by older clients who typically have been socialized to the medical model of intervention that requires little effort on their part. Unfortunately, the medication, while valuable in some instances in helping the patient regulate distressing affective, anxious, and cognitive symptoms, is not addressing the underlying pathology (i.e., the personality dysfunction) but is only providing symptom relief. Research on pharmacotherapy of PDs has mostly focused on Cluster B (dramatic, erratic, emotional) PDs, with generally promising, but preliminary results. For example, antidepressant medications have been found to show some positive effects for Cluster B patients (Ruegg & Frances, 1995), and antipsychotics have been found helpful for individuals with borderline PD, as they tend to reduce hostility, anxiety, and depression (Links & Steiner, 1988). The interested reader is referred to Soloff (1990) for an engaging and detailed review of pharmacological therapy for the PDs. Regrettably, pharmacotherapy studies typically have focused on younger and middle aged individuals. Despite encouraging findings, it remains to be seen how results with younger clients apply to geriatric clients. Indeed, older clients are particularly sensitive to interactive effects of medications and usually have greater side-effect profiles than younger persons. Pharmacotherapy studies with older clients are sorely needed.

7.12.7 SUMMARY

Initially in this chapter, we described the major evolution of the diagnosis of PDs from *DSM-I* to *DSM-IV*. By the placement of PDs on their own Axis in *DSM-III* and listing of specific and requisite criteria for each disorder in *DSM-III-R*, there was a tremendous growth in our knowledge of PDs and accompanying assessment tools and treatment techniques. Although there has been a parallel increasing interest in the psychology of older adults, clinical and investigative interest in PDs in this population is at the nascent stage. Many theories of the etiology of PDs have also been proposed, and we have reviewed several major biological, cognitive, evolutionary, and biosocial theories. It is clear from our review that most of these theories have ignored lifespan and aging issues, and, thus, there has been little or no attention to the nature or stability of PD symptomatology in the elderly.

Despite recent advances in the field, accurate diagnosis of PDs in the elderly is still a significant concern for clinicians and researchers. We have noted that some *DSM* diagnostic criteria may be inadequate for older individuals, given the unique physical, cognitive, and social complications encountered by the aged. We have suggested that the apparent decline in prevalence rates of some disorders (i.e., borderline, histrionic) may not be due to a maturation of the individual but rather the inability of the current diagnostic system to identify the age-related manifestations of these disorders. Some symptoms of PDs are erroneously attributed to old age and subsequently dismissed. Clients and professionals may also focus on Axis I symptoms and neglect to appreciate fully the role of the underlying personality dysfunction.

We have also reviewed the major self-report personality inventories and structured interviews employed to evaluate PDs. In clinical practice, all of the devices have been applied, no doubt, to older persons. However, formal reliability and validity studies of these instruments with the elderly are lacking in the literature. Recently, it has been demonstrated that the SCID for Axis I disorders can be reliably administered to older psychiatric populations (Segal, Hersen, Van Hasselt, Kabacoff, & Roth, 1993; Segal, Kabacoff, Hersen, Van Hasselt, & Ryan, 1995), and similar studies for Axis II instruments are needed. In the absence of empirical verification, it cannot be assumed that self-report devices and structured interviews for Axis II disorders have acceptable operating characteristics for this unique population. Definitive comparisons between instruments are also needed to advance the field. Our knowledge about the treatment of PDs in the elderly is presently limited, and much work remains to be conducted in this domain.

We hope that in this chapter we have delineated the problems and issues in the etiology, diagnosis, assessment, and treatment of PDs in the elderly. There have been some promising studies on these topics, and we feel confident that the growing general interest in aging and in PDs will lead to new contributions to this inchoate area.

7.13.1 INTRODUCTION

Schizophrenia has been studied in detail from a psychological perspective. This research has focused on symptomatology, adaptive functioning, and cognitive impairments during the premorbid, early, and middle stages of the illness. In contrast to the huge volume of psychological research on schizophrenia in these earlier stages, there is considerably less research on schizophrenia and related conditions in late life. Understanding schizophrenia in late life is important for several reasons, including developing knowledge of the impact of aging on the illness, developing new treatments specifically targeted at older individuals, and understanding any differences between individuals with schizophrenia that has been chronic throughout the lifespan and individuals who develop schizophrenia late in life. With the aging of the population of the United States, the average age of psychiatric patients, including persons with schizophrenia, will increase as well. It is estimated that in 1997, there are 300 000 individuals over the age of 65 with a history of a schizophrenia diagnosis (Blazer, 1996), with many (20 000) still receiving institutional care of some sort (Hafner & Hambrecht, 1994). In addition, late-onset schizophrenia has been studied in considerably more detail in the early 1990s, with a number of interesting findings emerging regarding the similarities and differences between same-aged individuals with schizophrenia with early onset and those with a lifelong course of illness (Jeste et al., 1995).

This chapter focuses on the full range of psychological characteristics of schizophrenia, including clinical symptoms and phenomenology, cognitive functioning, adaptive skills, and treatments. Since schizophrenia has proven to be the most heterogeneous of all psychiatric conditions, the effects of aging on this condition would be expected to be very diverse and the developing research findings confirm this expectation. Symptoms, cognitive functions, and outcomes appear to vary greatly across elderly patients with a history of schizophrenia, ranging from complete disappearance of symptoms with stable residence in the community (Harding, Brooks, Ashikaga, Strauss, & Breier, 1987a, 1987b; Harding, Zubin & Strauss, 1992) to stays in chronic care hospitals of more than seven consecutive decades with complete dependence on others for all of their needs (Davidson et al., 1995). Thus, the extreme variability across individuals seen in schizophrenia in earlier life appears magnified in late life.

7.13.2 CONCEPTIONS OF SCHIZOPHRENIA AND IMPLICATIONS FOR RESEARCH ON SCHIZOPHRENIA IN LATE LIFE

Schizophrenia was initially described as a condition that developed in late adolescence and led to a deterioration in cognitive functions and behavior. The specifics of the deterioration have been in dispute since that time. Although Kraepelin (1919) referred to schizophrenia as "dementia praecox," it is not clear that he meant that schizophrenia was a condition which led to progressive deterioration in cognitive and behavioral functioning. It is clear, however, that his general perspective was that after the development of the illness, a full return to the previous level of functioning is almost never expected. In contrast, Bleuler's (1911/1950) conception of the illness allowed not only for a full remission of symptoms but also for considerable variation in symptom severity during the active illness itself. Thus, from the very first detailed descriptions of schizophrenia there has been controversy regarding the course of the illness and, by implication, the level of adaptive and cognitive impairment expected in older individuals with the illness.

Onset age has also been a controversial issue in the conceptions of the illness. Kraepelin delineated dementia praecox from paraphrenia, thus subdividing the illness on the dimension of age of onset. Paraphrenia was described as an illness of late onset, with predominantly persecutory (i.e., paranoid) delusions and minimal additional impairments. Hallucinations, if present, were not a central feature of the illness and delusions were nonbizarre. In the *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* (American Psychiatric Association [APA], 1993), all hallucinations are required to be tactile or olfactory, not auditory, and must be related to the theme of the delusion. Patients with paraphrenia are classically described as lacking major changes in their affective response, and their level of motivation, and having preserved cognitive functions (Kraeplin, 1919). Their symptoms were seen as also remitting spontaneously with considerably more frequency than in dementia praecox. Bleuler disputed this conception, arguing instead that schizophrenia could develop in later life and that it was possible for a late onset of schizophrenia. Thus, the Bleulerian approach to the conception of the illness was that there was minimal difference in the characteristics of the illness seen as a function of onset age.

There has been controversy and evolution in diagnostic criteria for schizophrenia. Since the late 1970s, there has been considerable revision in diagnostic criteria for schizophrenia, with one of the major changes focusing on the issue of age at onset and the diagnosis for the disorder. The first of the new American diagnostic criteria, Research Diagnostic Criteria (RDC; Spitzer, Endicott, & Robins, 1978), required onset of symptoms between the ages of 16 and 45 for a diagnosis of schizophrenia. The rule-out for late onset was also present in *DSM-III* (APA, 1980), but was removed from the revision of these criteria in *DSM-IIIR* (APA, 1987). *DSM-IV* (APA, 1993) criteria also allow for schizophrenia to be diagnosed in individuals with an onset of symptoms at any age. No differences in symptomatology are required as a function of age of onset. One of the problems, of course, with diagnosing schizophrenia in later life is that many dementing conditions, including subcortical dementias such as Parkinson's disease and cortical dementias such as Alzheimer's disease, often have psychotic symptoms as a component of their symptom presentation (Jeste, Wragg, Salmon, Harris, & Thal, 1992). This situation can lead to complications in the initial diagnosis of schizophrenia.

7.13.3 DIAGNOSIS OF SCHIZOPHRENIA AND RELATED CONDITIONS IN LATE LIFE

Schizophrenia, as established by US and international criteria, is defined by the presence of characteristic symptoms, a clear decline in overall adaptive functioning, a minimum duration of illness, and the absence of other factors that could have caused the symptoms, such as affective disorder, substance abuse, brain dysfunction, or other general medical conditions (seizure disorders, etc.). Related conditions include schizophreniform disorder (illness meeting all criteria for schizophrenia other than the duration requirement), delusional disorder (a disorder with a single prominent, nonbizarre, delusion but not enough additional symptoms to meet criteria for schizophrenia), and schizoaffective disorder. As noted above, a major problem in diagnosing a new onset of any of these disorders in late life is the fact that degenerative dementing illnesses often have psychotic features as a symptom (Jeste et al., 1992). Thus, a careful cognitive assessment, including follow-up evaluation, is required at the time of diagnosis to rule out the presence of an alternative dementing condition. Neurological or neuroimaging assessment to rule out a cerebrovascular accident is also prudent.

One of the complexities of confirming a continued diagnosis of any of these disorders in individuals with a lifelong course of illness is that of ruling out alternative influences on symptoms. Aging-related physical illnesses and their consequences, including vascular disease, diabetes, and pulmonary problems, may cause cognitive impairments similar to those seen in schizophrenia. Thus, knowledge of current medical status is more important in generating a diagnosis of schizophrenia and related conditions in late life.

7.13.4 EPIDEMIOLOGY OF SCHIZOPHRENIA AND RELATED CONDITIONS IN LATE LIFE

Schizophrenia is well accepted to have a lifetime prevalence of around 1% of the population, across all cultures. Data suggest that there are slightly more male than female patients who meet diagnostic criteria for schizophrenia (Lewine, 1981), although onset age is quite important in determination of sex ratios of newly incident cases. Female patients are known to have a generally later age of onset for the illness (Faraone, Chen, Goldstein & Tsuang, 1994), although this finding may not hold true for patients who have a positive family history for schizophrenia in a first-degree relative (Albus & Maier, 1995). Prevalence of schizophrenia in late life is also a function of survival of early-onset cases, since schizophrenia has significant mortality associated with it. Most estimates of mortality associated with schizophrenia suggest that the first few years of illness are most dangerous, with accidents, suicide, and homicide accounting for mortality in these early periods. The large numbers of very old long-stay patients found in public psychiatric facilities in both the US and the UK suggest that long-stay patients as a group do not necessarily have an extremely abbreviated life expectancy. Two large-scale whole-hospital studies have found that female long-stay patients outnumber male patients (Davidson et al., 1995; Leff, Thornicroft, Coxhead, & Crawford, 1994), but differences in gender-related life expectancy might account for these findings.

There are an estimated 20 000 early-onset geriatric schizophrenic patients residing in chronic psychiatric hospitals in the US. In addition, there are another 200 000 living in nursing home care and an additional unknown number residing in community care (Meeks et al., 1990). It is not known how many former schizophrenic patients are living in relative remission in the community, but the results of some studies (Harding et al., 1987a, 1987b, 1992) suggest that this number may be substantial. Thus, the prevalence of diagnosable schizophrenia will be less than the sum of all cases still surviving who at one time carried a diagnosis of schizophrenia.

7.13.4.1 New Incidence of Schizophrenia in Late Life

Studies reviewed by Harris and Jeste (1988) suggested that approximately 15% of patients with a first episode of schizophrenia were over the age of 60 at the time of first psychiatric admission. In nearly every one of these studies, the proportion of females was greater than that of males in the new onset cases. These studies are often limited by virtue of being hospital admission studies and therefore fail to identify those cases who manifest the disorder but do not seek or otherwise obtain treatment. In a large-scale population-based prospective study, Castle and Murray (1993) examined the new-onset cases of schizophrenia in a London borough. They found that the average age of onset for males (31.2 years) was ten years younger than that of females (41.1 years) and that the prevalence and associated characteristics of the illness did not differ markedly as a function of the breadth of the schizophrenia criteria that were used. The male/female ratio changed as a function of age of onset, with the ratio at 1.6 to 1 for onset from ages 16 to 25 and 0.2 to 1 for onset age after 76. Patients with late onset were also much less likely to have a family history of schizophrenia, but some increase in familial prevalence of affective disorders was found in these patients. Previous studies of late-onset schizophrenia have suggested that late-onset schizophrenic patients typically have good adaptive functioning before the onset of illness, with some increase over normative expectations in the prevalence of schizoid or paranoid personality (Harris & Jeste, 1988).

7.13.4.2 New Incidence of Related Conditions in Late Life

A few studies have examined the characteristics of paraphrenia (i.e., late-onset delusional disorder) and compared it with schizophrenia. Parsons (1964) reported a prevalence of "late paraphrenia" of 0.17 to 0.24 cases per hundred community-dwelling elderly. Christenson and Blazer (1984) reported a 4% prevalence of paranoid delusions in community-dwelling elderly. Flint, Rifat, and Eastwood (1991) found a high incidence of "organicity" in the paraphrenia cases as compared with patients with late-onset schizophrenia. Yassa and Suranyi-Cadotte (1993) compared 20 patients with late-onset schizophrenia with 20 patients with late-onset paraphrenia. The incidence of paraphrenia was 4% of the total admissions over a 7-year period to a geriatric inpatient service, which was the same prevalence as for first-episode schizophrenia. Patients with paraphrenia were more likely to have had a concomitant physical illness and were less likely to have had a premorbid picture of personality abnormalities. These patients were also less likely to have a relapse after successful neuroleptic treatment.

Thus, many cases of schizophrenia apparently develop late in life, with several distinct epidemiological characteristics that separate them from early-onset cases and from related disorders with late-life onset. The prevalence of late-onset paraphrenia is more difficult to estimate, but is probably much less than that of schizophrenia. Since one-third of all cases of schizophrenia may have onset after age 50, the expected population prevalence of late-onset schizophrenia may be 0.33%, which is at least twice that of estimates of the prevalence of paraphrenia.

7.13.5 GENERAL OUTCOME OF SCHIZOPHRENIA IN LATE LIFE

Schizophrenia has long been noted for its variability in outcome, with a tendency toward negative outcomes dominating. Only about one-third of patients who meet diagnostic criteria for schizophrenia are able to resume adaptive functioning with any success and as many as one-third are chronically impaired and largely dependent on others for care on a lifelong basis (Wyatt, 1991). Comprehensive outcome studies suggest a wide variance in overall outcome (Ciompi, 1980). Although regional trends in mental health care may have as great an influence as the disorder itself on prevalence of patients with extremely long inpatient stay, a considerable number of schizophrenic patients have a very negative outcome with extended stays at high levels of care. Hospital-based studies have suggested that large numbers of geriatric patients with schizophrenia still reside in chronic psychiatric hospitals with low levels of functioning (Arnold et al., 1995; Davidson et al., 1995). These patients often have a relatively early age of onset, severe negative symptoms, poor adaptive functioning (both before and after the onset of initial symptoms), and severe cognitive impairments. Although some of these patients may be discharged from the hospital, many long-stay patients are simply referred to nursing home care (White et al., in press). Among the characteristics of patients who are difficult to discharge in late life are belligerent and hostile behaviors (White et al., in press), including both verbal and behavioral aggressiveness.

In contrast to hospital-based studies which tend to paint a fairly negative picture of outcome in the disorder, one comprehensive study has suggested that many individuals with an early diagnosis of schizophrenia go on to be discharged from the institution and to live in the community for decades with modest to no residual symptoms. The Vermont longitudinal study (Harding et al., 1987a, 1987b, 1992) suggested that many individuals with a diagnosis of schizophrenia in early adulthood are residing in the community, with modest to adequate adaptive, occupational, and interpersonal functions. Since this study was based in a rural state, which varies from urban areas in terms of levels of support and intactness of the community, the applicability of this study to patients from urban and suburban catchment areas is unclear. A study of community-dwelling geriatric schizophrenic patients (Bartels, Mueser, & Miles, 1997) based in the nearby state of New Hampshire found that there was considerably more impairment in adaptive functioning and clinical symptoms than reported in the Vermont study.

7.13.6 OUTCOME OF ACUTE PSYCHIATRIC ADMISSION IN LATE LIFE

While studies of chronic hospital populations may paint a gloomy picture of outcome in the disorder, there are some data from recent studies of acute care of geriatric patients with an acute admission for schizophrenia that also raise some questions about the outcome of even acute psychiatric care in the elderly patient with schizophrenia. Studies of nongeriatric first-admission patients (Loebel et al., 1992) suggest that over 90% of first-admission patients are in a state of remission within one year. Statistics for readmissions of patients with a previous history of schizophrenia are typically similar. While approximately 60% of acutely admitted nongeriatric psychiatric patients are discharged to the care of relatives, with another 30% being referred to some community residence, and only about 5% referred directly to chronic care (Keefe & Harvey, 1994), the two studies previously published on outcome of acute psychiatric admissions in geriatric patients suggested that only 50% at most of all acutely admitted patients who had been residing in the community returned to their former residence (Mulsant et al., 1993; Rockwood, Stolee, & Brahim, 1991). The geriatric schizophrenic patients in those two studies had a very high rate of referral to nursing home care (33% in Mulsant et al.) or long-term psychiatric hospitals (33% in Mulsant et al. and 20% in Rockwood et al.). These data suggest that there is a high risk for any single acute psychiatric treatment of a geriatric patient with schizophrenia to result in a referral to long-term care.

Explanations for this situation are complex. It is possible that acute psychiatric admissions in geriatric patients with schizophrenia are precipitated as much by medical or social crises as they are by exacerbation of symptoms of the illness. If there is an illness or other adverse event affecting a caregiver, a psychiatric admission may be precipitated, with the change in social environment precluding a return to the prior residence. An additional possibility is that what appears to be an admission for psychiatric reasons is actually precipitated by the onset of a degenerative dementia, such as Alzheimer's disease. The current set of short-term outcome studies do not allow for this possibility to be ruled out. Thus, it is not clear if schizophrenia alone, or if additional neurological or medical conditions are responsible for the relatively adverse outcome of geriatric acute psychiatric care.

7.13.7 CLINICAL SYMPTOMS IN LATE-LIFE SCHIZOPHRENIA

Clinical symptoms have been studied in both early- and late-onset cases of late-life schizophrenia. Symptoms of the illness are typically characterized in terms of three different dimensions: positive symptoms (i.e., florid), including delusions and hallucinations; negative symptoms (i.e., deficit symptoms), including reductions in affective response, language output, and motivated behaviors; and disorganized symptoms, including formal thought disorder, inappropriate affective, and bizarre behavior (Andreasen, Arndt, Alliger, Miller, & Flaum, 1995). For years, clinical lore held that positive and disorganized symptoms were "burned out" and that only negative or deficit symptoms would be detected in late life, even in long-stay institutionalized patients (Bridge, Cannon, & Wyatt, 1978). Several studies have suggested that this conception is partially to mostly incorrect.

In a large-scale study of chronically institutionalized schizophrenic patients ranging in age from 25 to 95 (Davidson et al., 1995), negative symptoms manifested an increase in severity over the age-range studied, while positive symptoms manifested a decrease. The severity scores for negative symptoms in this population were very elevated compared with those seen in younger patients. The decrease in severity of positive symptoms, however, was such that even the oldest of the patients studied manifested positive symptom severity scores at the 40th percentile for the standardization sample for the rating scale used (the Positive and Negative Syndrome Scale: PANSS; Kay, 1991). The severity of negative symptoms in the geriatric patients in this sample was found to increase slightly at a one-year follow-up of the sample, with no statistically significant decrease in positive symptoms (Putnam et al., 1996). This result is in contrast to studies of younger chronic schizophrenic patients (Mueser, Douglas, Bellack, & Morrison, 1991; Pogue-Geille & Harrow, 1984, 1985) where negative symptoms did not worsen in severity at similar follow-up intervals. In a study of formal thought disorder (Harvey, Lombardi et al., 1997), roughly parallel findings were seen. Geriatric chronically institutionalized patients manifested more severe poverty of speech and less severe "positive" thought disorders (e.g., derailment, tangentiality, loss of goal, and circumstantiality) than younger chronically institutionalized patients.

In a comparative study of late-onset, acutely ill patients with schizophrenia and early-onset chronic patients, paranoid symptoms were significantly more common on the late-onset cases (Jeste et al., 1995). In addition, late-onset patients were more likely to have better lifelong functioning, including marriage and a stable work history. A previous study (Harris, Jeste, Krull, Montague, & Heaton, 1991) had suggested that the deficit syndrome was present in approximately 30% of older patients with schizophrenia, with this prevalence probably not elevated from that seen in younger patients. When the stability of the deficit syndrome was examined in a large sample of geriatric chronic patients (Putnam et al., 1996), a high degree of cross-temporal stability was noted. Finally, White et al. (1994) used confirmatory factor analysis to compare the structure of symptoms in poor-outcome geriatric schizophrenic patients, divided on the basis of their level of cognitive dysfunction, with younger poor-outcome patients. No differences in the factor structure of clinical symptoms were found between older and younger patients or between the geriatric patients who varied in their level of cognitive impairment. The authors concluded that since schizophrenic cognitive impairment did not affect the structure of symptoms, it may be an instrinsic aspect of poor-outcome schizophrenia.

Any assessment of clinical symptoms in chronic schizophrenic patients, especially those with a long and often uninterrupted institutional stay, must seriously consider the role of iatrogenic factors. While life in a chronic care institution may not be likely to sustain the presence of positive symptoms, the level of impoverishment of the environment, years of treatment with antipsychotic medication, and the low staff-to-patient ratio could easily be argued to influence negative symptom severity. Although length of institutional stay had no relationship with the severity of negative symptoms in the Davidson et al. (1995) study, all patients had already been in the hospital for at least a decade. As in other discussions of cognitive functioning, chronic institutional care cannot be ruled out as a contributory factor to the severity of negative symptoms as measured in those studies. The results of longitudinal studies of early-stage patients with schizophrenia (Knight, Roff, Barrnet, & Moss, 1979) suggest that more severe negative symptoms early in the course of illness predict a more adverse outcome, and multiple cross-sectional studies of patients at approximately the same age suggest that negative symptoms are more severe in patients with a chronic course of illness and greater deficits in life skills. Positive symptom severity has been demonstrated to have no cross-sectional or longitudinal relationship with outcome (Green, 1996). More severe symptoms of disorganization, especially communication disorder, are associated cross-sectionally with poor outcome (Keefe et al., 1987). Thus, the most tempered interpretation of the data suggests that negative symptoms may start out worse in those patients with a lifelong stay in a chronic psychiatric hospital, with a late-life worsening where the institutional stay itself may affect symptom severity in certain patients.

7.13.8 COGNITIVE FUNCTIONING IN LATE-LIFE SCHIZOPHRENIA

Cognitive impairment is a very common symptom in schizophrenia, being present across the entire course of the illness (Kraeplin, 1919; Saykin et al., 1994). While a full discussion of the characteristics of cognitive impairment is beyond the scope of this chapter (see Gold & Harvey 1993 for a specific review of that symptom), it should be noted that deficits in academic functioning, relative to classmates, are identified in preschizophrenic individuals as early as the first grade (Crow, Done, & Sackler, 1995). Cognitive impairment appears to be stable within patients over time, across various follow-up intervals, and to predict outcome in the illness (Gold & Harvey, 1993). It should also be noted that there are many changes in cognitive functioning with aging in the normal population. While the domain of aging-related changes is enormous and beyond the scope of this chapter, several general points can be made. Major aging-related changes occur in motor speed and in memory functions, while the level of change in long-term memory and ability to access and utilize previously learned material is much more modest. As a consequence, baseline functioning can be estimated from performance on tests of old learning such as reading and vocabulary, because of the minimal aging-related changes in these areas. For a complete review of aging and neuropsychology, the reader is referred to Albert and Moss (1988). Since schizophrenic patients at their first episode often score 2 to 3 standard deviations below normal comparison groups (Saykin et al., 1994) or standardization samples, the possibility of detecting cognitive decline with aging is reduced because of floor effects. At the same time, it should be noted that the types of cognitive operations that change with normal aging (new learning and recall, concentration and attention, psychomotor and visuomotor speed) are the deficits most commonly noted in schizophrenic patients early in life. Thus, aging-related changes are likely to maximally impact those functions most impaired in schizophrenia earlier in life.

In younger schizophrenic patients, the typical assessment of cognitive functioning has either used assessment with clinical neuropsychological tests or with experimental measures of attention and memory. Across these studies, significant impairments have been found in learning and memory, attention, and executive functioning (see Gold & Harvey, 1993 for a review of these findings in younger patients), with lesser impairments noted in most other cognitive functions (Braff et al., 1991). In older schizophrenic patients, prominent cognitive impairments resembling dementia have also been reported. For example, in the Davidson et al. (1995) study, over 60% of the geriatric chronic schizophrenic patients would have met *DSM-IIIR* criteria for dementia in addition to schizophrenia. Similar findings were reported by Arnold, Franz, and Trojanowski (1994) in a separate sample. As demonstrated below, one of the issues that has been addressed in research on cognitive functioning is a comparison of the cognitive performance profiles of geriatric patients with schizophrenia, both early and late-onset, to the cognitive impairments seen in degenerative dementing conditions such as Alzheimer's disease (AD). Spurred by preliminary reports of an elevated prevalence of AD in postmortem brain specimens from patients who have a hospital chart diagnosis of schizophrenia (Prohovnik, Dwork, Kaufman, & Wilson, 1993), a number of studies have compared the cognitive profiles of patients with these two disorders.

One of the problems that develops in the assessment of geriatric patients is that of test selection. Patients who meet criteria for dementia may not be able to meaningfully complete many clinical neuropsychological tests, with their scores reflecting floor effects (Harvey, Mohs, & Davidson, 1993). One of the solutions that has been employed (Harvey et al., 1992) is the use of global screening measures, such as the Mini-Mental State Examination (MMSE; Folstein, Folstein, & McHugh, 1975 or a global assessment measure such as the Clinical Dementia Rating (CDR; Berg, 1988). These instruments have the advantage of being able to provide a global estimate of the level of cognitive functioning of the individual. They are limited by their focus on the cognitive impairments seen in degenerative dementia and their failure to include many of the content areas that are relevant to schizophrenia, such as executive functioning.

Studies of global estimates of cognitive functioning in patients with late-life schizophrenia have suggested that as many as 60% of geriatric chronically hospitalized patients have MMSE scores in the range suggestive of dementia. Davidson et al. (1995) used a cross-sectional design to compare MMSE scores in chronically hospitalized patients ranging in age from 25 to 95. There was a consistent linear relationship between MMSE scores and age, with the mean MMSE of patients who were aged 25 to 35 at 27 ("questionable impairment") and the mean MMSE of 85 to 95-year-olds only 9.6 ("severe dementia"). Even when low levels of premorbid education and age are considered (Crum, Anthony, Bassett, & Folstein, 1993), these scores are extremely low. There was a linear 3 MMSE points per decade reduction over the age-span of the patients studied. In contrast, in AD MMSE scores change an average of 3 points per year (Morris et al., 1993). When the geriatric patients who were still in the hospital were followed up 1 and 2 years later (Harvey, White et al., 1995) there was no measurable change in MMSE scores for the sample as a whole, the IntraClass Correlation Coefficient (ICC) was over 0.85 at each assessment, and one-month stability of the MMSE was found to be over 0.90 (ICC). When the sample of patients in the Davidson et al. sample was compared with similar-age, long-stay patients from the UK, there were no differences in their MMSE scores (Harvey, Leff, Trieman, Anderson, & Davidson, in press). In addition, MMSE scores of chronic schizophrenic patients in other US hospitals are strikingly similar across institutions (Gur et al., 1996).

These data suggest that globally estimated cognitive functions appear to manifest age-related differences, although these scores do not decline at a rate consistent with a degenerative dementia such as AD (Mohs, 1995). Further evidence for dissimilarity to AD was provided by Harvey, Lombardi et al.(1996), who used a battery of neuropsychological tests that was developed to assess the nature and progression of cognitive impairments in AD. At a one-year follow-up, none of these cognitive functions showed any evidence of decline. In addition, the profile of impairment was quite different from that seen in AD. A delayed recall memory deficit is the first reliable sign of mild AD (Welsh et al., 1991), with this deficit not progressing over time and being uncorrelated with overall MMSE scores (Morris et al., 1993). In the Harvey, Lombardi et al. study, delayed recall deficits were correlated with MMSE scores more strongly than any other measure. Further evidence of the dissimilarity of cognitive performance profiles in AD and geriatric schizophrenia is provided by the results of a cross-sectional study comparing late and early onset geriatric schizophrenic patients, nongeriatric schizophrenic patients, patients with AD, and normal controls on a expanded version of the Halstead—Reitan neuropsychological battery (Heaton et al., 1994). Patients with AD were found to perform worse than all schizophrenic patients on a measure of delayed recall, with the schizophrenic patients performing worse on several other summary measures. A very similar result was obtained by Davidson et al. (1996), who compared schizophrenic and AD patients who were matched on global cognitive impairment as measured by MMSE scores. Patients with AD were more impaired on delayed recall and less impaired on verbal and visuo-motor skills than schizophrenic patients who had similar MMSE scores. No differences in rate of learning were detected. Both of these studies suggest that schizophrenic patients are differentially impaired compared with patients with AD and both were careful to rule out alternative causes of cognitive impairment in their samples.

The results of these studies, combined with prospective studies of postmortem characteristics of geriatric schizophrenic patients failing to find evidence of AD-related neuropathology in the majority of cognitively impaired patients with schizophrenia (Arnold et al., 1995; Powchik et al., in press; Purohit et al., 1993), can be interpreted to conclusively demonstrate that the profound cognitive impairments seen in geriatric long-stay schizophrenic patients are not always due to degenerative dementia. What is considerably less clear, are the characteristics of cognitive impairment in geriatric schizophrenic patients and any possible differences between late- and early-onset cases, as well as the associations between outcome and cognitive impairments. In the Heaton et al. (1994) study, no differences in global neuropsychological summary scores were found between similar-aged early- and late-onset geriatric schizophrenic patients and no cognitive performance differences were found as a function of age in the schizophrenic sample. Similarly, Hyde et al. (1994) reported no age-related differences in cognitive functions in a cross-sectional study of schizophrenic patients ranging in age from the 20s to the late 60s. In contrast, several other studies of a large sample of extremely chronic institutionalized patients have found major age-related differences in both global indices of cognitive functions (Davidson et al., 1995) and in specific neuropsychological measures (Harvey, Leibman et al., in press; Harvey, Lombardi et al., 1995).

In terms of the specific characteristics of cognitive impairments seen in geriatric schizophrenic patients, Harvey, Powchik, Mohs, and Davidson (1995) compared geriatric chronic schizophrenic patients with either absent-mild or moderate cognitive impairments, defined by global ratings of a general clinical severity measure for dementia, on a battery of memory tests that have been demonstrated in brain-injured populations to be differentially sensitive to dysfunctions in the temporal and frontal lobes. They found that there were large differences in memory performance associated with global cognitive impairments and that patients, regardless of their level of cognitive impairment, tended to manifest patterns of performance consistent with either a temporal-lobe or frontal-lobe memory deficit. Paulsen, Heaton, Sadek, Perry, and Jeste (1995) also performed a comprehensive neuropsychological evaluation of profiles of memory impairment in schizophrenic patients, dividing their geriatric patients on the basis of cortical, subcortical, or unimpaired profiles. Cortical profiles include deficits in learning, recall, and recognition memory, while subcortical profiles include preserved recognition memory and increased benefits from cuing and encoding assistance. They found about one-third of the patients manifested an unimpaired profile, with 50% manifesting a subcortical profile. Only 15% of the patients manifested a cortical pattern of impairment. These results are quite consistent with the findings of Harvey, Powchik et al., who found that recognition memory performance did not vary across patients who differed considerably in their global level of cognitive impairment. In a study of verbal fluency performance, geriatric chronically hospitalized schizophrenic patients were found to be more impaired on phonemic fluency than younger chronic patients, with no age-related differences in category-based fluency when education differences between these two samples were considered (Harvey, Leibman et al., in press). Both groups of patients performed at least 2 to 3 standard deviations below age and education-corrected mean on category fluency and 1.5 to 2 standard deviations below the mean on phonemic fluency. An additional finding of some importance is that estimates of premorbid intellectual attainment (i.e., the Wide Range Achievement Test-Revised [WRAT-R; Jastak, 1984] reading subtest) were correlated with overall cognitive status in geriatric patients, but not nongeriatric patients. This suggests a possible bias effect that should be considered in later studies, as the WRAT-R or other similar tests are often employed as estimates of premorbid cognitive status in studies of cognitive functions in younger schizophrenic patients (O'Carroll, Walker, & Dunan, 1992).

In an examination of the long-term effects of psychosurgery in chronic schizophrenia, Harvey et al. (1993) studied 72 chronically hospitalized schizophrenic patients on a neuropsychological battery, comparing patients who had experienced a leukotomy with a sample matched for age, education, and overall cognitive status who had not. Consistent with earlier studies of leukotomized patients at younger ages (see Joschko, 1986 for a review), no major differences in cognitive functioning were found. These data suggest that a frontal lobe lesion that may disconnect the cortex and striatum does not interact with aging in chronic schizophrenia to produce even greater cognitive impairment, although there are some interpretive problems with the results. The geriatric chronic schizophrenic patients without leukotomy performed so poorly on tests sensitive to frontal lobe lesions, including the Wisconsin Card Sorting Test (WCST; Heaton, Chelune, Talley, Kay, & Curtiss, 1993), that it would be almost statistically impossible for the leukotomized patients to perform more poorly and reveal a differential performance deficit.

The results of these studies highlight the problem in studying cognitive performance in schizophrenic patients across wide ranges of age, chronicity, and severity of illness. Some of the inconsistent results may simply be the result of subject selection processes. The subjects in the studies conducted by Heaton and colleagues (Heaton et al., 1994; Paulsen et al., 1995) were largely outpatients residing in the community, in contrast to the subjects we studied, who had been continuously hospitalized for decades. Since more severe cognitive impairment is a powerful correlate of poor outcome in younger schizophrenic patients (Addington, Addington, & Maticka-Tyndale, 1991; Perlick, Mattis, Stastny, & Teresi, 1992), there is no reason to expect that extremely bad-outcome geriatric patients would not also have more severe impairments than those patients who are functioning adaptively in community. In the Hyde, Nawroz, Goldberg, Kleinman, and Weinberger (1994) study, relatively poor-outcome patients were studied, but younger and older patients were matched in WRAT-R scores in order to equalize premorbid intellectual functioning. As noted above, if WRAT-R scores are correlated with cognitive impairment in geriatric patients, matching on this variable would create a sample of geriatric patients who are preselected for reduced levels of cognitive impairment.

The previous research has revealed several important cohort effects when younger and older chronically hospitalized patients are compared. Geriatric chronic patients are consistently found to have a later age of first psychiatric admission and lower levels of formal education than younger patients (Arnold et al., 1995; Davidson et al., 1995). These differences have the potential of obscuring the interpretation of differences in cognitive functioning between the samples, because education and onset age have both been previously demonstrated to influence performance on cognitive tests. Performance differences between early and late-onset patients have the potential of being influenced by the correlates of chronic schizophrenia, including treatment and lifelong histories of social isolation, ostracism, and failure.

One area where age effects were not detected was in a set of studies examining the prevalence of age disorientation in chronic schizophrenia and affective disorder (Harvey, Lombardi et al., 1995; Lombardi et al., 1996). Age disorientation has been studied extensively by Crow and colleagues (Crow & Stevens, 1978; Liddle & Crow, 1984), with the consistent finding that approximately 25 to 33% chronic schizophrenic patients underestimate their age by 5 years or more. This finding has been demonstrated not to be caused by history of treatment, premorbid functioning, length of current hospital stay, age of onset, or age of the patients (Buhrich, Crow, Johnstone, & Owens 1988). Harvey, Lombardi et al. found that the prevalence of age disorientation was relatively stable, at approximately 40% from age 35 to age 75 in a sample of 393 chronically hospitalized schizophrenic patients. Age-related differences in cognitive functioning were found only in the patients who manifested age disorientation. Lombardi et al. found a similar rate of age disorientation (33%) in chronically hospitalized patients with affective disorders. These data suggest that one of the principal features of the cognitive impairment in schizophrenia may be orientation deficits. These deficits may be caused by impairments in episodic memory functions, which lead to faulty updating of personal information, in the same way that these memory impairments lead to poor performance on formal tests of memory functioning. Since only a portion of the patients manifest age disorientation, it cannot be due to some global factor associated with institutionalization. Furthermore, age disorientation was not associated, in either schizophrenic or affective patients, with history of premorbid functioning, including education, or history of somatic treatment, including leukotomy, insulin coma, or ECT, replicating previous findings (Buhrich et al., 1988). These data suggest that certain types of memory impairment may be correlated with poor outcome, regardless of diagnosis, and also clearly indicate that not all of the aspects of cognitive impairment in geriatric institutionalized schizophrenic patients could be attributed to aspects of institutional stay.

The main findings associated with the study of cognitive functioning in late-life schizophrenia is that there is very little evidence for the development of types of cognitive impairments that are qualitatively different from those seen in younger schizophrenic patients. While some studies find no age-related differences in cognitive performance, others do, with the principal variation between the studies being the nature of subject samples. The primary change appears to be a worsening of memory performance, in line with expected changes associated with normal aging, although this worsening still does not lead to performance as poor as seen in Alzheimer's disease. The association between extremely poor outcome and profound cognitive impairment leads to interpretive problems because of the very long length of stay and extensive treatment experienced by these patients. Since only a subset of these patients manifest age disorientation or other profound cognitive impairments, it is not possible that all aspects of their impairment are caused by institutional stay. Assuming that institutional stay and its correlates (e.g., medication treatment) have the potential to cause some of the cognitive impairments seen in geriatric chronically institutionalized patients, the variability across patients in level of impairment suggests that there may be individual difference factors that predict vulnerability to these effects. Identification of these factors is a useful target for further research.

7.13.9 ADAPTIVE IMPAIRMENT IN LATE LIFE SCHIZOPHRENIA

One of the principal sources of negative outcome in schizophrenia is a deficit in adaptive life functioning (Perlick, Stastny, Mattis, & Teresi, 1992; Serban & Gidynski, 1979; Tessler & Manderscheid, 1994). Many schizophrenic patients manifest severe and persistent disability because they are unable to care for themselves and become dependent on others for their care. Some of these impairments are more often present in patients with the negative symptoms (Mueser, Bellack, Douglas, & Wade, 1991) of schizophrenia as well as in patients with more severe cognitive impairment (Breier, Schreiber, Dyer, & Pickar, 1991). Patients who are dependent on others for their care are typically not more seriously affected by the positive symptoms of the disorder (Pogue-Geile & Harrow, 1985). Previous behavioral interventions in schizophrenia have often focused on remediation of these deficits in adaptive life functions (Hogg & Hall, 1992; Liberman, Mueser, & Wallace, 1986; Paul & Lenz, 1977), with some suggestions that pharmacological interventions should also be targeted at these types of deficits (Davidson & Keefe, 1995). As noted above, in younger chronic schizophrenic patients the presence of severe cognitive impairments is often correlated with the presence of these adaptive deficits (Green, 1996).

Limited information is available on adaptive functioning deficits in geriatric patients with schizophrenia. The available information suggests that the range of adaptive functioning is quite wide and that the level of care received by the patient is often correlated with their adaptive skill. Kincaid et al. (1995) studied 339 geriatric chronically hospitalized inpatients with schizophrenia, finding that clinical ratings of self-care and personal hygiene accounted for 9% of the variance in global ratings of severity of overall functional, cognitive, and behavioral impairment. Harvey, Davidson et al. (1997) developed the Social-Adaptive Functioning Evaluation (SAFE) scale, which was designed to evaluated overall adaptive dysfunction in geriatric institutionalized patients. They reported that total scores on the measure were strongly associated with the overall severity of cognitive impairment, as measured by the MMSE. In addition, the overall level of impairment was quite high in their population. For example, very severe impairments were found, on the average, for neatness and maintenance, money management, orientation and mobility, communication skills, and friendships, while impairments at a level that was considered "severe" were found on nine other measures of social, instrumental, and self-care skills. When a sample of 140 patients were followed prospectively for up to 3 years, it was found that deficits in the general areas of impulse control and self-care were quite predictive of discharge and placement. Patients with poor impulse control were likely to remain hospitalized, while patients with better self care were more likely to be discharged to a community setting. Social functioning did not discriminate between three different placement outcomes: remaining hospitalized, being referred to the community, or being transferred to a nursing home. In a study of over 800 geriatric psychiatric patients followed for 3 years during a period of downsizing of their psychiatric hospital, White et al. (in press) found that the presence of severe adaptive deficits was less strongly correlated with discharge from chronic care than the presence of hostile and belligerent behaviors. In patients who were discharged, however, severe deficits in adaptive functioning were more common in patients referred to a nursing home than in those discharged to the community.

In another study examining geriatric psychiatric patients residing outside of chronic hospitals and receiving community-based residential care, Bartels et al. (1997) evaluated patients with schizophrenia, major depression, and bipolar affective disorder. The severity of clinical symptoms was evaluated with the Brief Psychiatric Rating Scale-Expanded version (Lukoff, Liberman,& Nuechterlein, 1986) and with the Specific Levels of Functioning Scale (SLOF; Schneider & Streuening, 1983). The SLOF is a 43-item rating scale that comprehensively evaluates social, self-care, and community living skills, as well as disruptive behaviors. Schizophrenic patients, in addition to having more severe psychotic symptoms, were more impaired on all aspects of social and instrumental functioning than community-dwelling patients with affective disorders. These data suggest that the impairments in adaptive skills that characterize younger patients with schizophrenia are also present in late life, even in community-dwelling cases. Thus, severe adaptive deficits are present in many community-dwellers as well as in chronically hospitalized patients with schizophrenia.

In contrast, the results of the Vermont longitudinal study (Harding et al., 1987a, 1987b, 1992) suggest that some geriatric individuals with a history of schizophrenia are able to successfully adapt to life in the community and live there for extended periods without ever receiving any mental health services. Early identification of which patients are likely to have this type of adaptive success is not yet possible. When this constellation of characteristics predicting adaptive success is identified, early interventions for patients with a poor prognosis will be easier to target.

7.13.10 TREATMENT OF SCHIZOPHRENIA IN LATE LIFE

There is no specialized literature on the treatment of late-life schizophrenia with psychological interventions. At the same time, there is no information suggesting that current psychological treatments would be less effective in this type of population. Principal psychological interventions for schizophrenia with demonstrated efficacy are skills-based "rehabilitation" approaches and family intervention approaches designed to reduce expressed emotion (EE). Since EE approaches are applied to acutely ill patients, their applicability to geriatric schizophrenic patients with an early age of onset is limited. No specific EE research for late-life acute schizophrenia has been published up to 1997, although this may be a critical area for investigation. In particular, since many late-onset schizophrenic patients are referred to nursing home care directly from an acute psychiatric admission, assessment of EE characteristics at home may provide useful information in identifying those acutely ill late-onset patients who are at high risk to be referred to nursing home care because of negative aspects of their home life.

In contrast, skills-training approaches appear to be indicated for many of the geriatric patients (Bellack & Mueser, 1993). Since deficits in adaptive functioning are apparently extremely common in institutionalized and community-dwelling geriatric populations, this intervention would appear, at least superficially, to be likely to provide benefit to many of these patients. It is unclear how many of these geriatric patients have received such treatment earlier in their illness, without benefit, and how many have simply received "warehouse" institutional treatment or have been "dumped" into the community without follow-up plans. Previous studies suggest that even very severely ill younger patients may benefit from this treatment (Corrigan, Wallace, Schade, & Green, 1994), indicating that this population could be targeted for such an intervention.

A cautionary note is provided by the clear description by Green (1996) of cognitive barriers to such treatment. Since these interventions are essentially learning-based, deficits in the ability to learn with exposure, in performance on tests of vigilance, and in executive functioning have been demonstrated to markedly interfere with the success of these interventions in younger chronic schizophrenic patients. Since many geriatric patients with a chronic course of institutionalization manifest profound deficits in learning and memory, as described above, these patients would appear to be at high risk of failure in rehabilitation-type treatments (Mueser et al., 1991). Until techniques for cognitive enhancement are better supported with empirical research (see Vol. 18 (1992) of *Schizophrenia Bulletin* for a discussion of limitations in this regard), the application of social-instrumental skills-training approaches with geriatric patients with cognitive impairments appears to be quite likely to be unsuccessful.

Psychotropic medication for geriatric patients with schizophrenia is the most common treatment. While these interventions are not presently in the domain of clinical psychology, understanding of the issues involved in this type of treatment is important for any professional involved in the treatment of this population. As with many other drugs, dosing of geriatric patients is most useful at lower levels, a fact of which some treating physicians are apparently unaware. Geriatric patients are apparently more susceptible to the side effects of these medications as well. The reader is referred to a review paper by Jeste, Lacro, Gilbert, Kline, and Kline (1993) which addresses these issues, and others, in detail.

7.13.11 CONCLUSION

Schizophrenia is a lifelong illness that does not disappear with aging. Although some patients with schizophrenia have a good outcome in late life, the majority, both institutionalized and community dwelling, manifest severe deficits in adaptive functions. Clinical symptoms appear to be severe in most patients studied, with the level of symptoms seen across care settings arguing strongly against the idea that these symptoms burn out with age. Cognitive impairment appears to be a strong predictor of adaptive deficits and patients with a particularly poor outcome may actually show cognitive decline into the range of functioning commonly associated with dementia.

Schizophrenia appears to have a fairly high new case incidence in late life, with as many as 15% of all geriatric cases having had initial onset after age 65. These patients appear to resemble good-prognosis early-onset cases, other than for the high prevalence of females. Data on specific psychological treatments for late-life schizophrenic patients are completely lacking and are clearly necessary. As is clear from the data in this chapter, schizophrenia in late life is not benign and is associated with considerable disability in adaptive functioning and a clear burden on society or relatives. Development of effective treatments, psychological and pharmacological, for late-life schizophrenia is a clear goal for the future.

7.14.1 INTRODUCTION

Since the 1950s, increasing attention has focused on changes in sleep with advancing age. This chapter reviews what sleep is, how sleep is measured, and the major theories of sleep, and then focuses on the changes that occur in sleep with advancing age. Prevalent sleep disorders found in elderly populations are described, current methods of evaluation and treatments of these disorders discussed, and special emphasis is placed on adapting the interventions to the specific needs of elderly populations.

7.14.1.1 Measurement of Sleep

Sleep is an active process with changes occurring in physiological systems. Traditionally, sleep is studied by recording brain waves (EEG or electroencephalography), eye movement (EOG or electro-oculography), and muscle tension (EMG or electromyography). Information gained from these three channels of information allow the identification of the different stages of sleep. When additional clinical information is necessary, other systems such as heart rate, respiration, level of oxygen in the blood, limb movements, body position, and blood pressure may also be recorded. The recording of these variables is called a polysomnograph (PSG).

For diagnostic purposes, sleep is usually recorded for one full night. Since there may be some adaptation problems to the laboratory environment (referred to as "the first night effect"), for further assessment or for research purposes, sleep may be recorded for additional nights.

There have been many technical advances in the field of sleep with portable PSG now being available. Many of the same variables that are recorded in the laboratory can now be recorded in the patient's own home. Two major advantages of portable PSG are that the patient is more comfortable and relaxed at home and that it is less expensive than laboratory PSG. Much research is being conducted to determine the minimum number of channels of information necessary to screen for specific sleep disorders (Ferber et al., 1994).

An alternative approach for objectively measuring sleep/wake is the wrist actigraph. An actigraph measures wrist movement and significantly correlates with EEG for distinguishing wake from sleep (Sadeh, Hauri, Kripke, & Lavie, 1995). Wrist activity has been shown to provide valid and reliable measurements of the sleep/wake rhythm in elderly patients and has been used for elderly populations who might have difficulty with traditional EEG recordings such as elderly patients with insomnia (Hauri & Wisbey, 1994) and nursing home patients (Ancoli-Israel, Jones, et al., 1991). An additional advantage of wrist activity is the ability to record for consecutive 24-hour periods. The limitation of wrist actigraphy, however, is that it cannot distinguish between different sleep stages.

7.14.1.1.1 Sleep stages

Sleep is traditionally divided into two major states: rapid eye movement (REM) sleep and non-rapid eye movement (NREM) sleep. NREM sleep is further divided into four sleep stages. Each of the stages differs from one another in the amplitude and frequency of the brain waves, in the type of eye movements, and in the presence or absence of muscle tone. The four NREM stages roughly parallel a "depth of sleep" continuum, with arousal thresholds generally increasing from a low threshold in stage 1 to the highest threshold in stage 4. Stage 1 is the transitional phase between wakefulness and sleep and is characterized by low-voltage, mixed-frequency EEG and slow eye movements. Stage 1 sleep usually comprises about 2–5% of the night. Stage 2 sleep is considered the onset of sleep and is characterized by sleep spindles and k-complexes. Stage 2 usually comprises about 45–75% of the night. Stages 3 and 4 sleep are called deep sleep or slow-wave sleep and are characterized by high-amplitude, slow-frequency delta waves. Slow-wave sleep usually comprises 25% of the night in younger adults but almost 0% in the elderly. REM sleep is characterized by low-voltage, high-frequency EEG with minimal or no muscle tone and with rapid eye movements. REM sleep, which is also called dream sleep, comprises 20–25% of the night.

REM sleep is often called paradoxical sleep since it is characterized by high-frequency brain activity which resembles wakefulness. However, the arousal threshold is high (i.e., the subject is difficult to awaken) and there is motor paralysis or muscle atonia. This paralysis is believed to be a protective mechanism which keeps the dreamer from acting out dreams. REM sleep is also characterized by episodic bursts of rapid eye movements and irregular heart rate, respiration, and blood pressure.

7.14.1.1.2 Sleep cycles and architecture

NREM sleep and REM sleep alternate through the night in a cyclic fashion. The individual moves through the four NREM stages, then gradually returns to stage 2 sleep from which REM sleep is entered. NREM sleep generally comprises 75–80% of the sleep period, whereas REM sleep comprises 20–25% of the sleep period.

7.14.1.2 Theories on the Function of Sleep

Although we sleep for about one-third of our lives, the function of sleep remains enigmatic and controversial. The generally held assumption is that sleep is an essential and unavoidable condition. The strongest research evidence for the essential role of sleep comes from long-term sleep deprivation studies. For example, animal studies have shown that after 2–3 weeks of total sleep deprivation, rats die, suggesting that sleep is critical for survival (Glotzbach & Heller, 1996). These types of observable changes that occur during the process of sleep deprivation stimulated the development of several theories which have attempted to explain the underlying mechanisms of sleep.

There are four major theories on the function of sleep. The thermoregulatory theories of sleep suggest that sleep serves as a time for the organism to produce or to dissipate heat in order to maintain optimal body temperature (Nakao, McGinty, Szymusiak, & Yamamoto, 1995). The homeostatic drive hypothesizes that the sleep/wake system is driven by a homeostatic process (Borbely, 1994), i.e., as the duration of wakefulness (and therefore the length of time since the last sleep period) increases, the propensity for sleep increases. While the organism sleeps, this drive gradually decreases. The model suggests, however, that independent of the duration of the wake period, sleep is more likely at some circadian times than others. A third theory, that of memory consolidation, suggests that during some periods of sleep (i.e., REM sleep), certain types of memories are consolidated for the purpose of long-term storage (Carskadon & Dement, 1994). The fourth theory is that of the restorative function of sleep. This theory suggests that the physiological and biochemical degradation that occurs during the day is restored during deep sleep (Rechtschaffen, 1994). Each theory has data supporting it as well as data contradicting the models. The only conclusion that can be drawn at this time is that, although the full function is not yet known, sleep is crucial for survival.

7.14.1.3 Changes in Sleep Associated with Aging

Various epidemiological studies and population-based surveys have consistently indicated that up to 50% of people over age 65 experience some disruption of sleep (Foley et al., 1995). However, studies have indicated that these sleep disturbances were associated with poor physical health and depression (Monjan & Foley, 1996). Studies of healthy older people have shown that sleep complaints were infrequent, notwithstanding the presence of increased night-time wakefulness and decreased time in deeper stages of sleep (Prinz, Vitiello, Raskind, & Thorpy, 1990).

7.14.1.3.1 Objective sleep studies

The general findings, based on objective PSG measurements, are that in contrast to younger people, older people spend more time in bed but sleep less, and are more easily aroused from sleep. The most prominent finding is the profound decrease in slow-wave sleep (stages 3 and 4).

As people age, sleep becomes increasingly fragmented, resulting from both a rise in the number of transient arousals and an increase in the total amount of time awake throughout the night. Increased night-time wakefulness may cause increased daytime fatigue, daytime napping, and increased likelihood of falling asleep during the day. The question of whether daytime naps are the cause or the consequence of disturbed night-time sleep needs to be further explored.

Daytime napping is common among elderly populations. While surveys vary in their estimations of the frequency of napping in elderly populations, there is consensus that the amount of napping increases with age. Prinz (1977) reported that 25% of elderly people studied took a daytime nap, while Wauquier and colleagues reported that 80% of healthy elderly subjects napped on average for 30 minutes a day (Wauquier, Van Sweden, Lagaay, Kemp, & Kamphuisen, 1992).

Results obtained from objective studies which focused on daytime sleepiness also showed an increase in daytime sleepiness as measured by the multiple sleep latency test (MSLT). The MSLT consists of 4–5 opportunities to go to sleep at 2 hour intervals and is considered to be the standard for evaluating daytime sleepiness. Older people fell asleep faster than younger adults on all nap opportunities (Dement, Seidel, & Carskadon, 1982).

7.14.1.3.2 Subjective reports

Subjective complaints of the elderly tend to be consistent with PSG findings. Older people report taking longer to fall asleep, sleeping less at night, waking more often during the night, waking up early in the morning, and napping more during the day (McGhie & Russel, 1962).

Using a sample of over 9000 community-dwelling individuals over the age of 65, Foley et al. (1995) found that over half of the sample reported at least one of five of the most common complaints: trouble falling asleep, waking up during the night, waking up too early, needing a nap, and not feeling rested. Sleep complaints have also been found to relate to measures of depression (Benca, Obermeyer, Thisted, & Gillin, 1992).

7.14.1.3.3 Gender differences

Gender-related differences have been noted in sleep of the healthy elderly. A meta-analysis of PSG data conducted by Benca et al. (1992) showed that older women may sleep better than older men. Women also appeared to maintain sleep better than men (Rediehs, Reis, & Creason, 1990). It is noteworthy that older women were more likely than older men to complain of sleeping difficulties and thus receive hypnotics more often (Ohayon & Caulet, 1995).

Hormonal changes associated with menopause impact sleep. Menopause has been associated with both subjective complaints of insomnia, and objective changes including increased sleep latency, decreased REM sleep, and decreased total sleep time. Treatment with supplemental estrogens may help to alleviate some of these sleep disturbances (Wooten, 1994).

7.14.2 DISORDERS OF SLEEP

Sleep disturbances in elderly people may be due to primary sleep disorders (e.g., sleep-related respiratory disturbances or periodic movements in sleep)—the frequency and severity of which tend to increase with age—or they may be secondary to a variety of medical, psychiatric, pharmacologic, and psychosocial factors. Chronic sleep disturbances may also exacerbate illness, cause discomfort and frustration, and may be related to depression. The daytime effects of chronic sleep disturbances include impaired cognition, confusion, slowed psychomotor functioning, and increased risks of injuries due to falls, thus impairing the quality of life of the patients and their families.

7.14.2.1 Sleep-disordered Breathing

Sleep-disordered breathing (SDB), also called sleep apnea, is a repetitive process of respiratory cessation during sleep, often resulting in arousals during which respiration resumes. There are three types of SDB: (i) obstructive sleep apnea involves a collapse of the airway which partially or completely blocks the air flow, (ii) central sleep apnea results from failure of the respiratory neurons to stimulate the motor neurons that mediate respiration, (iii) mixed sleep apnea involves both a central and an obstructive component. Respiratory events involve either a complete cessation of breathing (apnea), or a partial obstruction of the airway resulting in a reduction in breathing (hypopnea). The number of apneas per hour of sleep (apnea index; AI) plus the number of hypopneas per hour of sleep (hypopnea index; HI) determine the respiratory disturbance index (RDI). SDB is generally diagnosed when a patient has 10 or more respiratory events per hour of sleep (i.e. $\text{RDI} \geqslant 10$) or five or more apneas per hour of sleep (i.e., $\text{AI} \geqslant 5$) (Kryger, 1989).

Several factors, acting alone or in concert, have been hypothesized to contribute to the presence and severity of SDB. These factors include age; obesity; micrognathia; jaw or nasal deformities; thyroid, pituitary, or neurologic impairments; and alterations of respiratory reflexes during sleep (Shepard, 1989). It has been demonstrated that the effect of weight on SDB is at least as great as chronological age, even above age 70 (Bliwise et al., 1987).

7.14.2.1.1 Symptoms

Snoring and daytime sleepiness are the two most common symptoms of SDB. Snoring itself is a partial obstruction of the airway, and is associated with a number of health problems including hypertension and cardiovascular disease (Fairbanks, Fujita, Ikematsu, & Simmons, 1987). The snoring of sleep apnea patients, especially those with OSA, is often so loud that it disrupts the sleep of the bed partner. Therefore, the bed partner is often the first to suspect a breathing disturbance.

Another common symptom of SDB is excessive daytime sleepiness which likely results from the frequent nocturnal awakenings caused by the apnea episodes as well as from the hypoxia experienced at night. The resulting daytime sleepiness can have serious implications as patients with SDB may have difficulty sustaining wakefulness while working, conversing with others, or driving a car.

With repeated decreases in respiration, patients with SDB often experience hypoxemia which may lead to other health problems such as hypertension, cardiac arrhythmias, myocardial infarction, and stroke, which have long-term health implications (Shepard, 1992).

7.14.2.1.2 SDB and hypertension

Many studies have shown a relationship between snoring and hypertension with those reporting frequent snoring reporting a higher prevalence of diagnosed hypertension (Hoffstein, 1990). In fact, research has shown that about one-third of all hypertensives have SDB (Ancoli-Israel, Bliwise, & Mant, 1993). Apneas are accompanied by a transient elevation of blood pressure suggesting that SDB may contribute to sustained systemic hypertension.

7.14.2.1.3 SDB and cognitive impairment

In addition to excessive daytime sleepiness, sleep apnea is also associated with problems in concentration, attention, and memory during the day (Bliwise, 1993). Numerous researchers have demonstrated a relationship between oxygen desaturations in patients with sleep apnea and cognitive functioning (Ancoli-Israel & Coy, 1994). Bliwise (1991) demonstrated that SDB has an effect on cognitive function independent of age and other risk factors; however, some researchers have not successfully replicated these findings (Findley, Presty, Barth, & Suratt, 1991). In elderly sleep apnea patients with no other health problems, this relationship may not be as strong (Hayward et al. 1992). It is important to note that extremely healthy elderly are not representative of the older population in general who typically suffer from one or more health problems in addition to sleep apnea. Although controlled studies have not been done, it appears that treatment of SDB may result in some improvement in cognitive functioning (Derderian, Bridenbaugh, & Rajagopal, 1988).

7.14.2.1.4 Mortality

Many investigators have studied the relationship between SDB and mortality (He, Kryger, Zorick, Conway, & Roth, 1988; Lavie et al., 1995), but few have studied the relationship in elderly. Ancoli-Israel, Kripke et al. (1996) reported that, in a population of community-dwelling elderly men and women, those with severe SDB had a significantly shorter survival time on follow-up than those with mild–moderate SDB or those with minimal or no SDB. Further, over 50% of the patients with SDB were more likely to die from cardiovascular disease, while only 35% of the subjects with minimal SDB died of the same cause. However, SDB was not predictive of death, while cardiovascular disease and pulmonary disease were. The relationship between SDB, cardiovascular disease, pulmonary disease, and mortality needs further exploration.

7.14.2.1.5 Prevalence

SDB is a common sleep disorder in elderly men and women, with most studies confirming that sleep apnea is more common in the elderly than in younger populations (Ancoli-Israel & Coy, 1994). In middle-aged adults (ages 30–60), the prevalence of SDB is estimated at 4% in men and 2% in women (Young et al., 1993). Ancoli-Israel and her colleagues have shown that 81% of those over 65 years had 10 or more respiratory events per hour of sleep, and 24% had five or more apneas per hour of sleep (Ancoli-Israel et al., 1991a). They also demonstrated that 33% of comparably aged inpatient populations, and 42% of an elderly nursing home population had at least five apneas per hour of sleep (Ancoli-Israel, 1989).

Few studies have been done examining the relationship between SDB and race. In a sample of older adults, it was found that although the prevalence of SDB was not different between Caucasians and African–Americans, the older African–Americans had more severe SDB (Ancoli-Israel et al., 1995).

7.14.2.1.6 Treatments

Some suggest that an RDI $\geqslant 20$ should be aggressively treated since significant mortality risks have been demonstrated at this level. Until about the late 1980s, tracheostomy was the only available treatment for sleep apnea. Since that time, a variety of therapeutic options have become available. The appropriateness and efficacy of each treatment varies from one patient to another, and should be assessed on an individual basis.

(i) Positive airway pressure

Nasal continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) are highly effective treatments of OSA, and these are the most commonly used nonsurgical treatments. Nasal CPAP acts by providing continuous pressure to the upper airway which prevents airway collapse (Sullivan & Grunstein, 1989). The CPAP system involves a mask worn over the nose at night which is connected via a hose to the CPAP machine. The pressure is adjusted by the prescribing physician until no more or very few respiratory events are seen.

(ii) Surgery

Some patients may be unwilling or unable to comply with CPAP or other treatments to control OSA. For such patients a surgical intervention may be appropriate. One of these surgical treatments is uvulopalatopharyngoplasty (UPPP) which is intended to widen the airway passages by shortening the uvula, removing unnecessary tissue, and tightening the flabby muscles of the airway. This surgery may improve snoring, and has been shown to decrease the number of apneas during the night to the level achieved by CPAP in about 50% of patients (Powell, Guilleminault, & Riley, 1994). Since it is possible for snoring to decrease without improvement of SDB, follow-up evaluation of sleep is extremely important.

One of the advances in the surgical treatment of snoring is laser-assisted uvulopalatoplasty (LAUP) (Standards of Practice Committee of the American Sleep Disorders Association, 1994). A laser beam is used to shorten or remove the uvula and trim the soft palate which vibrates while breathing during sleep. This procedure may alleviate snoring without improving the severity of SDB, and sleep should be reassessed following treatment. LAUP is not recommended as a treatment for SDB.

(iii) Dental devices

Numerous dental devices have been developed to open the airway by holding the tongue or jaw forward in order to reduce snoring and OSA. These devices are quiet, cost-effective, simple to use, and may be particularly appropriate for patients who have difficulty using CPAP or are not appropriate for surgery. Although these devices successfully increase the size of the airway, the actual reduction in RDI varies greatly between patients (Lowe, 1994).

(iv) Medications

Tricyclic antidepressants such as protriptyline (Vivactil) and flouxetine (Prozac) are respiratory stimulants and may improve sleep apnea. The side effects of these medications and their interaction with other drugs a patient may be taking should be considered, especially in the elderly who may be taking multiple medications.

(v) Weight loss

Since obstructive sleep apnea results from a closing of the airway, excess fatty tissue in the neck area may be a contributing factor. Ancoli-Israel, Kripke et al. (1996b) reported that elderly men and women with sleep apnea had significantly higher body mass indices than those with minimal or no sleep apnea, supporting evidence that weight plays a significant role in the presence and severity of SDB.

(vi) Other treatment strategies

Several other factors which may exacerbate SDB should be addressed in the treatment of afflicted patients. Alcohol, which is sometimes used by men and women suffering from insomnia, has been shown to exacerbate sleep apnea (Taasan et al., 1981). Supine body position was found to increase SDB and snoring in some patients (Cartwright, Diaz, & Lloyd, 1991). Taking measures to avoid sleeping on the back may reduce the number of respiratory events. Some medications such as hypnotics, narcotics, and barbiturates may also exacerbate respiratory problems and reduce the patient's ability to wake up and breathe (Ancoli-Israel et al., 1993). These medications should be used with extreme care in the elderly who are more likely to suffer from SDB, and who also use sleeping pills more frequently than any other age group.

7.14.2.2 Periodic Limb Movements in Sleep

Periodic limb movements in sleep (PLMS), also called nocturnal myoclonus, is characterized by repetitive leg kicks during sleep, occurring every 20–40 seconds, lasting 0.5–5 seconds and causing brief arousals (Coleman, 1982). The precise mechanisms underlying PLMS are not well understood although numerous hypotheses have been proposed.

7.14.2.2.1 Symptoms

The primary symptom of PLMS is leg kicking during sleep. The kick may be as mild as a muscle twitch, or may be an involuntary jerk. An uncomfortable sensation builds up into a need to kick which relieves the sensations. Sometimes the patients themselves are not aware of the leg kicks, although bed partners usually are. Other symptoms of PLMS include insomnia, motor restlessness, excessive daytime sleepiness, and sometimes cold feet (Ancoli-Israel, Seifert, & Lemon, 1986; Coleman et al., 1982).

7.14.2.2.2 Clinical evaluation

Patients complaining of night-time awakenings or sleep-onset trouble may suffer from PLMS. Patients with PLMS may also report daytime sleepiness as a result of the night-time sleep fragmentation resulting from arousals associated with the leg jerks. Interviewing the bed partner along with the patient provides additional information.

The only way to make an accurate diagnosis of PLMS is to record leg movements as part of a complete PSG. The number of leg jerks recorded per hour of sleep is called the myoclonus index (MI). A diagnosis is made when there are five or more leg kicks per hour of sleep ($MI \geqslant 5$) each with an accompanying arousal. In patients with PLMS, periods of normal sleep alternate with disrupted sleep. The presence and severity of PLMS may vary from night to night (Mosko, Dickel, & Ashurst, 1988).

A related disturbance, restless legs syndrome (RLS), occurs more during the relaxed waking state. As summarized by Walters et al. (1995), patients experience "creeping" sensations in their legs. Moving the legs relieves this uncomfortable sensation, but the sensations return when the movement stops. Patients with RLS report difficulty falling asleep and symptoms may recur throughout the day or night. RLS is associated with caffeine intake, fatigue, exceptionally warm environment, prolonged exposure to cold, anemia, rheumatoid arthritis, and the last trimester of pregnancy. Almost all patients with RLS have PLMS, although the converse is not true.

7.14.2.2.3 Prevalence

The prevalence of PLMS in adults is estimated at 5–6% in the general population (Bixler et al., 1982). The prevalence increases with age, up to 45% in older populations, with no difference between men and women (Ancoli-Israel et al., 1991b).

Patients with PLMS sleep less than those with no leg jerks, and there is evidence for some sleep disturbance being associated with the leg kicks (Ancoli-Israel et al., 1991b). There is also evidence that patients with PLMS often suffer from SDB or narcolepsy (Coleman, Pollak, & Weitzman, 1979).

7.14.2.2.4 Treatments

PLMS is treated with medications and each treatment regimen has its advantages and disadvantages. Common treatments of PLMS include the use of sedative-hypnotics such as clonazepam or temazepam (Mitler, Browman, Menn, Gujavarty, & Timms, 1986), opiates such as Tylenol with codeine (Kavey, Walters, Hening, & Gidro-Frank, 1988), or levidopa/carbidopa (e.g., Sinemet or Sinemet CR) (Kaplan, Allen, Buchholz, & Walters, 1993). The fact that dopamine precursors and opiate drugs may alleviate PLMS in some patients suggests that one or both of these systems play a role in the pathophysiology of this disorder; however, both of these treatments are ineffective in some patients. Since many patients with PLMS also suffer from sleep apnea, a careful assessment of the sleep complaints should be conducted to determine whether SDB coexists with the PLMS since treatment of the PLMS with sedative-hypnotic medications may exacerbate sleep apnea. Whether the beneficial effects of long-term treatment with medications outweighs the risks associated with chronic use is yet unresolved.

7.14.2.3 Insomnia

The term "insomnia" (lack of sleep) refers to the complaint of an inability to initiate and/or to maintain sleep. Insomnia can be further divided into three subtypes: sleep-onset insomnia (difficulty in initiating sleep), sleep-maintenance insomnia (difficulty remaining asleep), and early morning insomnia (waking early and being unable to fall back to sleep). Many individuals experience a combination of the insomnia complaints. Younger adults are more likely to complain of sleep-onset insomnia whereas older adults are more likely to have sleep-maintenance or early morning insomnia, (Lichstein & Reidel, 1994). Insomnia is also defined by the duration of the disorder: transient insomnia refers to a very short-term insomnia that usually occurs in response to a sudden stress, short-term insomnia refers to a state that occurs over weeks and is often associated with acute medical or psychosocial factors, and chronic insomnia is a disturbance lasting months or longer.

Insomnia is the most common sleep complaint reported by elderly people. All epidemiological surveys that have evaluated the effect of age on sleep patterns have shown a higher prevalence of insomnia in older persons than in younger persons (Ford & Kamerow, 1989). Estimates of complaints of difficulties in falling asleep, of frequent or prolonged wakening, and of generally light and disturbed sleep range up to 40% for those 60 years of age and older (Miles & Dement, 1980), and estimates of severe insomnia complaints are more than 20% (Mellinger, Balter, & Uhlenhuth, 1985).

In addition to advancing age, female gender and concomitant health problems have been identified as important risk factors for insomnia (Klink, Quan, Kaltenborn, & Lebowitz, 1992). Women also tend to use more sedative medications to treat their insomnia than men (Mellinger et al., 1985). Individuals with chronic insomnia experience more psychological distress, are more preoccupied with somatic complaints, and utilize health care resources more often than good sleepers (Morin, Culbert, & Schwartz, 1994).

7.14.2.3.1 Clinical evaluation

Clinical evaluation of insomnia should encompass the various facets of the complaint. Insomnia should never be evaluated strictly as a night-time problem; rather the daytime effects on cognition and behaviors and the daytime behaviors that may contribute to the insomnia should also be examined (Morin, 1993).

(i) Clinical interview

As with any sleep complaint, a comprehensive clinical assessment includes a detailed medical and sleep history. The sleep interview usually examines the nature and the severity of the complaint, the daytime consequences of the insomnia, the environmental factors, the medication use, the dietary and smoking habits, the medical history, and the possibility for other sleep disorders.

Following the interview, Morin (1993) suggested that a functional behavioral analysis be conducted. The purpose of the functional analysis is to examine the antecedents, consequences, and the other controlling variables of the insomnia, and to identify the perpetuating factors. This understanding is essential for tailoring an intervention that is adapted to the specific difficulties of the individual. The assessment needs to be carried out with support and empathy and should focus on the patient's prebedtime routine, sleep incompatible activities, secondary gains, and typical responses to sleeplessness. The clinician may use and integrate information obtained by subjective daily sleep reports and by objective measurements. Compliance issues need to be addressed directly in individual discussions with the patient and, when possible, should involve the bed partners as they are most helpful in providing additional information.

(ii) Sleep diaries

Self-report measures are frequently used for assessment of the disturbance and for the evaluations of the treatment outcomes. Sleep diaries, also called sleep logs, are usually employed daily to collect descriptive data on sleep. A typical sleep diary is shown in Table 1. From the reported data, the total time in bed, total sleep time, and sleep efficiency can be calculated. Sleep diaries are useful for tracking treatment progress. Another advantage is that they demand active participation of the client. Despite the subjective nature of the sleep diaries, they tend to correlate significantly with PSG measures (Carskadon et al., 1976). Since insomnia is a subjective complaint, the treatment success, as defined by the patient, is more dependent on the patient's favorable perception of sleep than on objective changes.

(iii) Objective measurements

The usefulness of PSG for diagnosis of insomnia has been questioned. First, insomnia may be setting specific, thus laboratory PSG might not adequately represent the patient's insomnia as experienced at home (Hauri, 1983). Second, a single PSG might not detect chronic insomnia, given the nature of the disorder, since insomnia does not necessarily present every night, and repeated recordings are very costly. Conversely, it has been argued that PSG may be valuable for older patients since the presenting symptoms of insomnia may be secondary to sleep apnea, PLMS, or other sleep disorders that may have a similar clinical presentation to insomnia (Edinger et al., 1989). Lichstein and Reidel (1994) also conclude that PSG is indicated not only when there is a suspicion that other sleep disorders are present but also when insomnia treatments fail.

Wrist activity is an alternative objective measurement of the sleep–wake schedule. However, the results of actigraphy with insomnia patients may exhibit substantial disagreement with PSG results (Hauri & Wisbey, 1992). Nevertheless, actigraphy can be used effectively as part of psychological treatment to measure changes in sleep within subjects and can provide the patient with some reflection on the changes occurring in his or her sleep patterns.

Table 1 Sample sleep diary.

1. What time did you get into bed last night?
2. What time did you fall asleep last night?
3. How long do you think it took you to fall asleep?
4. How many times did you wake up during the night?
5. How long did it take you to fall back to sleep?
6. What time did you wake up in the morning?
7. What time did you get out of bed?
8. How did you feel when you woke up in the morning?
9. How much caffeine did you have yesterday?
10. How much alcohol did you have yesterday?
11. Did you nap? If yes, how many times and for how long?

Note. This questionnaire should be completed in the morning.

7.14.2.3.2 Etiology of insomnia

It is widely accepted that insomnia is a multifactorial symptom resulting from medical, behavioral, psychosocial, and environmental factors. *DSM-IV* (American Psychiatric Association, 1994) provides three categories for insomnia: primary insomnia, insomnia related to another mental disorder, and sleep disorders due to a general medical condition, insomnia type. The diagnoses are made on the basis of interview data. Chronic insomnia can have debilitating daytime consequences on mood, fatigue, performance, and motivation, as well as an adverse affect on an elderly person's quality of life and therefore on the public health system.

(i) Medical factors

The discomfort of medical conditions may disturb sleep, and some disorders, such as neurological and respiratory diseases, will directly alter sleep structure. Medical problems that are commonly associated with insomnia include neurological disorders, chronic obstructive pulmonary disease (COPD), cerebrovascular disease, headache, asthma, and any conditions that produce persistent pain (Wooten, 1994).

(ii) Psychiatric conditions

Sleep is also influenced by psychiatric conditions which can alter sleep patterns and architecture. It has been estimated that approximately 90% of depressed individuals exhibit some abnormality in sleep architecture (Reynolds, 1989). Depression has been related to early morning insomnia, although the most common finding was decreased REM latency (Benca et al. 1992). When sleep variables of elderly depressed individuals were compared with those of younger counterparts, the elderly show decreased sleep efficiency, decreased REM latency, decreased total sleep time, increased intermittent wakefulness, and decreased slow-wave sleep (Gillin et al., 1981).

(iii) Alcohol, caffeine, and nicotine

Alcohol, caffeine, and nicotine are all substances that are widely used (and abused), yet each can have a negative effect on sleep. Alcohol is the most commonly used nonprescription sleep medication. While it may initially decrease sleep latency, later in the night it causes sleep fragmentation, REM deprivation, and REM rebound. Alcohol use decreases with age, however, the sedating effects of alcohol may be more pronounced in elderly due to their decreased metabolic rate (Dufour, Archer, & Gordis, 1992). Furthermore, the combination of alcohol and hypnotics can also play a role in exacerbating existing insomnia.

Stimulant substances such as caffeine and food or drugs that contain caffeine (such as coffee, tea, certain sodas, chocolate, analgesics, bronchodilators, steroids, some antihypertensives, decongestants, and appetite suppressants) may produce insomnia as a side effect (Espie, 1991). Caffeine has been associated with an increase in sleep latency, decrease in total sleep time, and increase in spontaneous awakenings. Discontinuation of these substances may be associated with withdrawal symptoms of sleepiness, irritability, and depression (Diagnostic Classification Steering Committee, 1990). Nicotine may also produce insomnia and is related to lighter and more fragmented sleep.

(iv) Psychosocial factors

Life events (such as bereavement) and lifestyle behavior can affect sleep and instigate insomnia. Retirement and the lack of scheduled activities may cause more daytime napping (Kronholm & Hyyppa, 1985). Evidence shows that adhering to an active and structured schedule may be an important factor in maintaining satisfactory sleep (Hoch, 1991).

Physical activity has been related to improvement of both sleep onset and sleep maintenance. PSG reports of older adults who participate in regular exercise revealed more sleep consolidation (e.g., less wake time, more continuous and deeper sleep) than sedentary subjects (Edinger et al., 1993).

A diverse group of behaviors, sleep habits, and environmental variables tend to promote or impair sleep. Poor sleep habits, irregular sleep schedule, noise, room temperature, and changes in the sleep environment are related to sleep disruptions. Sensitivity to environmental factors increases with age and is also subject to individual difference.

(v) Cognitive factors

Patients with insomnia are more prone to cognitive arousals and anxiety than those with no insomnia (Lichstein & Fanning, 1990). Cognitive factors were identified by patients with insomnia as a more frequent source of sleep disruption compared with somatic complaints (Espie, Brooks, & Lindsay, 1988).

7.14.2.3.3 Pharmacological treatments

Older patients frequently take multiple prescription medications, often prescribed by more than one physician, as well as over-the-counter medications. Some of these medications may cause insomnia, contribute to daytime sleepiness, or exacerbate sleep apnea. Alcohol, beta blockers, bronchodilators, corticosteroids, CNS stimulants, decongestants, gastrointestinal drugs, cardiovascular drugs, and neurological drugs can all cause insomnia. Analgesics and benzodiazepines are known to cause daytime sleepiness. Antidepressants also affect sleep. Amitriptyline, sinequan, and trazodone are known to cause sleepiness, while buproprion, fluoxetine, paroxetine, sertraline, and venlafaxine are known to cause insomnia. Many antidepressants, such as desipramine, imipramine, and nortriptyline, can cause both insomnia and/or daytime sleepiness (Ancoli-Israel, 1996).

Pharmacotherapy is still the most commonly used therapy for insomnia in the elderly (Prinz et al., 1990), although it is complicated by age-related changes in pharmacokinetics and pharmacodynamics (Hicks et al., 1981). Sleep medication usage is disproportionally higher among older people, particularly among women.

There may also be adverse daytime effects including performance deficits (e.g., poor motor coordination, visual-motor problems), increased daytime sleepiness, and accidental injury (Roth, Roehrs, & Zorick, 1988). In addition, some hypnotics may alter sleep architecture by reducing slow-wave sleep and REM sleep. With continued use, tolerance can develop after only a few weeks, resulting in the return of the insomnia symptoms or requiring an increase in dosage in order to achieve the previous efficacy. Sleeping pills, therefore, when used inappropriately, can play a role in preserving and exacerbating insomnia rather than improving it. Withdrawal from hypnotics (especially abrupt cessation from long-acting drugs) may produce rebound insomnia, which is characterized by marked worsening of sleep and heightened anxiety. In addition, elderly are more likely to have disorders that can be aggravated by hypnotics such as respiratory, hepatic, renal, or cardiac disorders. As mentioned, hypnotics prescribed to patients who suffer from sleep apnea could exacerbate their oxygen desaturation and create serious medical risks (Gillin & Ancoli-Israel, 1992).

Elderly patients who are prescribed hypnotics should be given the lowest possible dose of a shorter-acting hypnotic for a short time period. The patient should be closely followed to decide if a renewal of the prescription is warranted.

All hypnotics impair performance while active; therefore, those with shorter half-lives and shorter duration of action have less impairment. Anterograde amnesia is a potential side effect of all hypnotics; however, the dose and duration will determine how severe the memory loss is. Since sleep itself produces amnesia, the interaction of the hypnotic with sleep onset will determine how much amnesia is experienced.

Rebound insomnia can also be caused by hypnotics, particularly those with short or intermediate half-lives. When the hypnotic is suddenly withdrawn, insomnia returns for several nights and the patient is tempted to resume taking the drug. For all these reasons, hypnotics are not recommended to be used on a nightly basis and should only be used for short periods of time.

All hypnotics, if given in adequate doses, will improve insomnia. The more commonly prescribed hypnotics include estazolam, flurazepam, quazepam, temazepam, triazolam, and zolpidem. The task is to determine the lowest adequate dose that promotes sleep with the fewest side effects. In addition, drug therapy should always be in conjunction with a nonpharmacological plan directed toward the underlying disorder.

7.14.2.3.4 Psychological treatments

The recognition of the role of psychological factors in creating, precipitating, or enhancing insomnia combined with acknowledgment of the limitations and the risks associated with long-term use of hypnotics prompted the development of nonpharmacological approaches for the management of insomnia. These alternative approaches include educational, behavioral, and cognitive interventions aimed at changing the maladaptive behaviors and attitudes toward sleep and insomnia.

(i) Sleep hygiene

Sleep hygiene is an educational approach for treatment of insomnia that was developed by Hauri and Linde, (1990). The basic premise of sleep hygiene is that poor behavioral habits (i.e., inadequate sleep hygiene) interfere with the maintenance of good quality of sleep and daytime alertness. Several habits may lead to disturbed sleep, for example, taking daytime naps; spending extended time in bed awake; keeping irregular sleep/wake schedules; excessive use of caffeine, nicotine, or other stimulants; exercise at inappropriate times; poor sleep environment; and engaging in exciting or emotionally upsetting activities close to bedtime. Providing basic knowledge about the structure of sleep and the factors that affect sleep constitute the core component of sleep hygiene. Table 2 lists the major rules of good sleep hygiene for the elderly.

Sleep hygiene has been incorporated into most psychological interventions for insomnia. Clinically, these instructions provide a good start for treatment. Hauri (1991) cautioned against giving a complete written list of sleep hygiene rules as that might overwhelm the patient. Instead, he recommended targeting a few rules which are pertinent to the patients' specific problem.

(ii) Stimulus-control therapy

Stimulus-control therapy, developed by Bootzin and Nicassio (1978), is based on the premise that sleep disturbances are behaviorally conditioned and therefore need to be reconditioned. The purpose of the intervention is to establish a consistent sleep/wake pattern, recondition the bed and bedroom as cues for sleep, and extinguish the maladaptive associations. Table 3 lists instructions for stimulus-control therapy.

The focus of the instructions is primarily to shorten sleep onset. For sleep-maintenance difficulties, the instructions are to be followed after awakening when the patient has difficulty falling back to sleep. Compliance is enhanced when the instructions are discussed individually and a rationale is provided for each rule. Two modifications of the rules have been suggested for older patients. For rules 2 and 3, those over the age of 60 are instructed to get out of bed after about 20 minutes, instead of 15 minutes. This recognizes that older individuals usually take longer to fall asleep than do younger individuals. The goals of rule 8 are to keep patients with insomnia from disrupting their sleep patterns by irregular napping and to prevent them from losing the advantage of the sleep loss from the previous night which increases the likelihood of faster sleep onset the following night. However, a short daily nap at the same time would be permissible. For those elderly patients with insomnia who feel that they need to nap, a short daily nap (30 minutes or less) or relaxation period as a nap substitute may be recommended (Bootzin & Engle-Friedman, 1987).

Table 2 Rules of sleep hygiene for the elderly.

1. Limit naps to less than 30 minutes per day
2. Take a walk both to exercise and to increase light exposure
3. Check the effect of medications on sleep
4. Avoid caffeine, alcohol, and tobacco
5. Limit liquids in the evenings
6. Keep regular hours

Table 3 Instructions for stimulus-control therapy.

1. Patient goes to bed only when sleepy
2. If not asleep within 15 minutes, patient gets out of bed, and does not return to bed until sleepy
3. When patient returns to bed, if not asleep within 15 minutes, gets out of bed again
4. Pattern is repeated until patient can fall asleep within a few minutes
5. Must avoid looking at the clock
6. Must get up at the same time each morning (even if only slept 2 hours)
7. Bed is used only for sleeping (not for watching television, reading exciting books, etc.)
8. All naps during the day must be avoided

Stimulus-control techniques have been shown to be effective with a variety of insomnia patients. Comparisons of stimulus-control interventions with placebo interventions have demonstrated superior sleep-latency curtailment for stimulus-control (Lacks, Bertelson, Gans, & Kunkel, 1996). Several studies reported improvement in sleep-maintenance insomnia in older patients (Morin & Azrin, 1988).

(iii) Sleep-restriction therapy

The approach to restrict time in bed and sleep duration in order to increase sleep efficiency was developed as a technique for the treatment of insomnia by Spielman, Saskin, and Thorpy (1987). It is based on the observation that many patients with insomnia spend excessive time in bed in futile attempts to achieve more sleep. Over time, the frustration and worry produced by excess awake time in bed serve to perpetuate the insomnia. Sleep-restriction therapy consists of curtailing the time spent in bed to the actual amount of time slept. The effects of restricting time in bed are twofold: first, this excess worry time is eliminated, and second, restriction may create an initial state of sleep deprivation, which itself produces more consolidated and satisfying sleep. Prescribed sleep-period durations from bedtime to arising time are based on self-reported sleep durations that are obtained from sleep diaries of the previous week. At first, patients may experience some sleep deprivation since they usually underestimate their amount of sleep, but this sleep deprivation may eventually work to reduce the sleep latency and to consolidate sleep. For example, if a patient reported sleeping 5 hours per night (out of 8 hours spent in bed) then the initial prescribed "sleep window" would be 5 hours per night. After sleep efficiency increases and the patient is "using effectively" the 5 hours for sleep, the allowed time in bed is increased by about 20 minutes each week, and this gradual increase is contingent on improved sleep efficiency. Implementation of the technique requires flexibility and adjustment to the individual patient and obviously a high level of cooperation and compliance. Table 4 lists the rules for sleep-restriction therapy.

Further modifications were added by Glovinsky and Spielman (1991) in order to increase compliance and to adjust the instructions to specific problems. For example, they included some flexibility with regard to setting the time in bed for patients with subjective perception of little or no sleep. For elderly patients, the sleep-efficiency criteria is lower by 5%. Research on sleep-restriction therapy, focused on older adults, showed good results (Friedman, Bliwise, Yesavage, & Salom, 1991). It has also been reported that sleep restriction combined with sleep hygiene and stimulus-control instructions can be effective for the treatment of sleep-maintenance insomnia in older patients (Gillin & Byerley, 1990). Lichstein and Reidel (1994) concluded that sleep-restriction therapy is probably the treatment of choice for geriatric insomnia.

A study examined the effects of sleep compression (restricted time in bed) combined with sleep education for older patients with insomnia (Riedel, Lichstein, & Dwyer, 1995). The study also looked at the differences between self-help techniques (using a guiding video) and therapist guidance. They found that the self-help insomniac group exhibited improvement on multiple sleep variables, but the addition of therapist guidance appeared to enhance treatment outcome for sleep latency, wake time after sleep onset, and sleep satisfaction. Interestingly, the sleep knowledge was equivalent for older patients with insomnia and no insomnia, suggesting that knowledge of age-related sleep changes may have a weaker influence than actual sleep-pattern differences on whether individuals consider themselves as having insomnia or not.

Table 4 Instructions for sleep-restriction therapy.

1. Patient is only allowed to stay in bed for the amount of time they think they sleep each night, plus 15 minutes. For example, if patient reports sleeping only 5.75 hours, they are allowed to stay in bed for 6 hours
2. Patient must get up at the same time each day. If normal waking time is 6.30 a.m., patient is allowed to go to bed at 12.30 a.m
3. Napping is not allowed
4. When sleep efficiency has reached 85%, the patient can go to bed 15 minutes earlier
5. This procedure is repeated until the patient can sleep for the desired amount of time

(iv) Cognitive interventions

Cognitive interventions for the treatment of insomnia are applications of the general principles of the cognitive model to psychotherapy as developed by Beck, Rush, Shaw, and Emery (1979), and others and further adapted specifically to the treatment of insomnia. The general principle of cognitive interventions is to focus on clarification and change of the maladaptive expectations, beliefs, and attitudes that the individual holds toward his or her problems; in this case, toward his or her sleep and sleeplessness. The cognitive change is ensued by using cognitive restructuring, reframing of the problem, challenging misconceptions, and enhancing the sense of self-control.

Morin, Stone, Trinkle, Mercer, and Remsberg (1993) described cognitive behavioral therapy for insomnia as an integration of behavioral, educational, and cognitive components which target the different facets of insomnia. The cognitive component is based on the principle of cognitive restructuring, applied by Morin (1993) to the special needs of the treatment of insomnia. The purpose of the cognitive intervention is to focus on dysfunctional beliefs and attitudes toward sleep and insomnia and to alter maladaptive attitudes that lead to or exacerbate sleep difficulties. Common misconceptions are held about sleep requirements, the causes for sleep difficulties, the consequences of insomnia and about the ability to control, predict, and promote sleep. These attitudes and misconceptions about sleep and sleeplessness may perpetuate a vicious cycle of insomnia, and may lead to or exacerbate existing sleeping difficulties. The fear of sleeplessness may then cause increased emotional arousal and anxiety that may create more problems in initiating and maintaining sleep.

Cognitive-behavior therapy sessions, as described by Morin, Kowatch, Barry, and Walton (1993), follow a three-step process: identification of the patient's specific dysfunctional beliefs, confrontation and challenging of those thoughts, and implementation of methods for revising and altering these thoughts with more rational and adjusted beliefs. A study conducted on elderly patients with insomnia showed that they exhibited more unrealistic sleep expectations, misattributed the causes of their sleep disturbances, and engaged in catastrophic thinking about the consequences of their insomnia, compared with normal-sleeper controls (Morin, Stone et al., 1993). Thus with elderly patients, the cognitive restructuring techniques should address the issue of normal changes in sleep with age versus pathological changes.

(v) Relaxation and biofeedback

A basic assumption behind various techniques of relaxation, meditation, and biofeedback is that the patients with insomnia are overaroused and anxious, and this arousal interferes with their ability to fall asleep and to resume sleep after being awakened in the middle of the night (Hauri, 1981). The purpose of the relaxation procedure is to teach the patients to relax so that they can fall asleep faster. It has been argued that the benefit may extend beyond the sleep problem and will facilitate a more general improvement in coping skills.

(vi) Summary

Two meta-analyses, conducted to examine the efficacy of psychological treatments for insomnia, summarized 59 and 66 treatment outcome studies, respectively (Morin et al., 1994; Murtagh & Greenwood, 1995). Both analyses concluded that nonpharmacological interventions produce a reliable and durable change in both sleep patterns and the subjective experience of sleep, compared with control groups. The improvement obtained by the psychological interventions was also maintained at short- and long-term follow-ups. Whereas Morin et al. (1994) concluded that the most effective single-therapy procedure was stimulus control and sleep restriction, Murtagh and Greenwood (1995) concluded that psychological treatments did not differ greatly in efficacy. Greater therapeutic gains were available for participants who were clinically referred and were not regular users of sedative hypnotics. It is possible that the drug users, because of their psychological reliance on hypnotics, had low self-efficacy for falling asleep naturally, which may have reduced expectations for improvement and consequently undermined treatment (Murtagh & Greenwood, 1995).

Although only a small number of studies focused on the elderly, the results show that insomnia in old age responds to psychological techniques. However, in a review, only five of the intervention studies with older adults included a no-treatment control group and the role of placebo has not been tested in geriatric insomnia (Lichstein & Reidel, 1994).

Studies have compared the efficacy of psychological vs. pharmacological therapies (McClusky, Milby, Switzer, Williams, & Wooten, 1991). Frequently, psychological treatments are used in combination with hypnotic therapy. In fact, there is a growing advocacy for a package approach combining both pharmacologic and behavioral interventions (Lichstein & Reidel, 1994).

7.14.3 CIRCADIAN RHYTHM CHANGES WITH AGE

The sleep/wake cycle is controlled by the body's circadian rhythms. The circadian rhythms, in turn, are controlled by the suprachiasmatic nucleus (SCN) located in the anterior hypothalamus. Studies have shown that surgical removal of the SCN results in animals taking multiple brief naps during the day and night rather than having one long sleep period at night.

Circadian rhythms are synchronized by external cues, or zeitgebers, such as light. Light enters the retina of the eye through the retinohypothalamic tract to the SCN. As the light intensity varies, our sleep/wake cycle varies. The circadian core body temperature rhythm and the circadian melatonin rhythm also interact with the timing and quality of sleep (Myers & Badia, 1995).

Much of the increased napping, daily fatigue, and daytime sleepiness in the elderly can be partially attributed to the breakdown in the body's circadian rhythm, manifested in the advancement of the rhythm and the decline in the rhythm amplitude (Bliwise, 1993; Vitiello, 1996). Czeisler et al. (1989) confirmed a phase advance of about 90 minutes and reduced amplitude of about 30% in the body temperature rhythms of older subjects compared with younger adults.

Circadian rhythm disturbances occur when the body's rhythm no longer matches that of the environment. One such common problem in the elderly is advanced sleep phase syndrome (ASPS). People with ASPS get sleepy earlier in the evening, around 8.00 p.m. If they were to go to bed at that point, they would most likely sleep for about 8 hours, waking up at 4.00 a.m. Most older people, though, do not go to bed early even if they are tired. Instead, they stay up until 10–11.00 p.m. Their bodies however, are still waking up at 4.00 a.m. Figure 1 illustrates the ASPS. In this way, older people are essentially depriving themselves of sleep by not allowing enough time in bed during the body's correct circadian phase to get sufficient sleep.

7.14.3.1 Bright-light Treatment

Studies of light exposure have shown that elderly living in the community are only exposed to 60 minutes of bright light a day, i.e., of 2000 lux or more. Alzheimer's disease patients living at home are exposed to 30 minutes of bright light a day (Campbell, Kripke, Gillin, & Hrubovcak, 1988). Studies on nursing home patients have shown that no

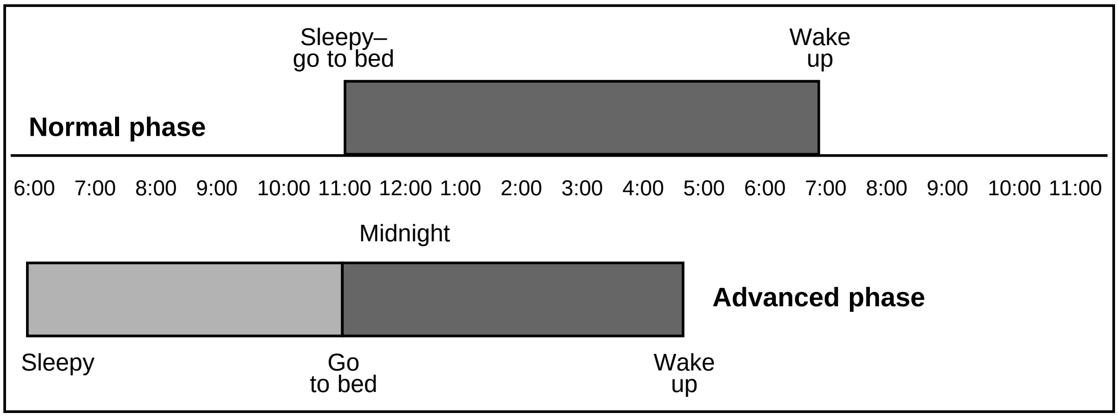

Figure 1 Advanced sleep phase syndrome. (Reprinted with permission of Mosby from Ancoli-Israel (1996).)

patient is ever exposed to over 2000 lux a day and on average, only 11 minutes are spent at levels over 1000 lux per day (Ancoli-Israel, Jones et al., 1991). Since light is such a strong zeitgeber, appropriately timed exposure to bright light can influence phase and amplitude of the circadian timing system (Czeisler et al., 1989). Specifically, bright-light exposure in the evening delays the circadian rhythm, i.e., pushes the rhythm forward so that the individual is no longer sleepy early in the evening. It has been shown that 2 hours of evening bright-light exposure (of at least 2500 lux) is beneficial for sleep maintenance insomnia in healthy older individuals (Campbell et al., 1995).

7.14.3.2 Melatonin

Melatonin, which is produced by the pineal gland at night, can reset sleep onset through its synchronizing effect on the internal biological clock (Dawson & Encel, 1993). With increasing age, the pineal gland secretes less melatonin (Reiter, 1995). The efficacy of administration of melatonin as a replacement therapy is a focus of growing interest. Haimov et al. (1995) reported a correlation between poor sleep and lower peak levels of melatonin in elderly patients with insomnia, suggesting that melatonin insufficiency may be a key variable in sleep disturbance of these older people. Garfinkel, Laudon, Nuf, and Zisapel (1995) conducted a follow-up study on 12 elderly patients with insomnia using a controlled-release formulation that provided effective concentrations of melatonin throughout the night. They found an improvement in sleep efficiency, and a reduction of the time awake after sleep onset during treatment, although total sleep time was not significantly different. The authors concluded that melatonin deficiency is a common cause of insomnia in the elderly and that replacement with controlled-release melatonin may effectively improve sleep quality in this population; however, patients should be screened for "melatonin deficiency" before administration of exogenous melatonin. These results were confirmed by Haimov et al. (1995).

Since the research on the efficacy of melatonin for improving sleep in general and for its specific efficacy on sleep consolidation in the elderly is in its first stages, more data are needed. Moreover, since melatonin is not regulated by the FDA and sufficient data are unavailable, caution should be taken with regard to the purity and dosage of the melatonin currently being sold over-the-counter and the time at which the melatonin is taken.

7.14.4 DEMENTIA AND SLEEP

Dementing illnesses include several nonreversible conditions (e.g., Alzheimer's disease, Parkinson's disease, Huntington's disease, multi-infarct dementia), and there is considerable evidence that dementia impacts sleep differently than the normal aging process (Bliwise, 1993). The sleep/wake rhythm in Alzheimer's disease (AD) patients has been found to be extremely disturbed (Ancoli-Israel, Klauber et al., 1996; Bliwise, Hughes, McMahon, & Kutner, 1995). As many as 70% of demented patients suffer from AD, and due to this high proportion of AD patients, most sleep studies include a majority of patients suffering from AD and often fail to distinguish between the specific type of dementia (Bliwise, 1993). Prinz et al. (1990) describe the sleep of AD patients as showing increased duration and frequency of night-time awakenings, decreased slow-wave and REM sleep, and daytime napping.

7.14.4.1 Laboratory Studies

Compared with nondemented control subjects, the waking EEG of dementia patients typically shows abundant diffuse slow activity, decreased alpha frequency, and other specific abnormalities associated with pathophysiological changes in the brain (Prinz & Vitiello, 1989). This slowing of EEG activity in dementia may cause distinguishing wake from sleep and differentiating between sleep stages to be very difficult. Temporal asymmetry frequently appears in both the waking and REM sleep EEG (Petit, Montplaisir, Lorrain, & Gauthier, 1992). Additionally, abnormalities in REM sleep measures (including REM percent and REM latency) are often found in AD patients, and may present only in the more severe stages of the disease (Reynolds, Kupfer et al., 1988).

7.14.4.2 Dementia and Depression

Demented patients presenting with depression may suffer from even more serious sleep disturbances than those with dementia in the absence of depression. This has been demonstrated with a PSG study comparing AD patients with age-matched depressives. This study showed that the depressed patients had even more disturbed sleep than the demented patients (Reynolds, Kupfer et al., 1988). In fact, elderly men and women with severe depression may appear to have symptoms of dementia (Reynolds, Hoch et al., 1988).

7.14.4.3 Nursing Home Patients

Sleep fragmentation has been shown to be extreme in institutionalized elderly (Ancoli-Israel, Parker, Sinaee, Fell, & Kripke, 1989). Disturbed sleep with frequent awakenings, night wandering, wakefulness, and confusion has been identified as one of the most common symptoms leading to the institutionalization of the elderly (Pollak & Perlick, 1991). Table 5 lists suggestions for dealing with sleep disturbances in this population.

Several attempts to objectively measure the sleep of nursing home patients with traditional EEG measures have had multiple problems. One drawback of EEG measurement is that the EEG wires themselves may exacerbate confusion and agitation in demented elderly (Cohen-Mansfield, Werner, & Freedman, 1995). A second problem is that the waking EEG in these patients shows diffuse or slow activity, often making it difficult to distinguish wake from sleep (Bliwise, 1993). In addition, both objective and observational sleep studies have demonstrated that the night-time sleep and the sleep/wake cycles of nursing home patients are extremely disrupted (Ancoli-Israel et al. 1989; Bliwise et al. 1995). Bliwise et al. (1995), using observational data collected by nursing home staff members, demonstrated that the level of night-time sleep fragmentation in AD patients was related to the severity of their dementia.

Ancoli-Israel and her colleagues (Ancoli-Israel, Klauber et al., 1996; Jacobs, Ancoli-Israel, Parker, & Kripke, 1989) conducted a series of studies using wrist actigraphy with nursing home patients. They computed the minutes of sleep and wake hour-by-hour, and found that, on average, over 24 hours, there was not a single hour that consisted of complete sleep or of complete wake; rather, a period of some sleep and some awakening occurred during each hour. Severely demented patients slept more in every hour of the 24-hour period than mild–moderately demented patients (Pat-Horenczyk & Ancoli-Israel, 1996). Times of most alertness were confirmed to be the meal times (Jacobs et al., 1989).

Previous results have shown great individual variation in sleep patterns and sleep pathology of cognitively impaired nursing home populations (Regestein & Morris, 1987). An exploration of the relationship between the severity of dementia and sleep found that overall, severely demented patients slept more both during the

Table 5 Dealing with sleep disturbances in nursing home patients.

1. Limit time in bed
2. Keep regular schedule of wake/sleep, meals, etc.
3. Avoid caffeine; make sure patients are not buying caffeinated snacks in the nursing home gift shop or getting gifts of chocolate from family and friends
4. Encourage time cues: serve meals at a table at the same time each day and avoid eating meals in bed; place large clocks and calendars around the home
5. Avoid frequent naps; limit to one daily nap
6. Keep night-time noise to a minimum
7. Keep resident rooms as dark as possible at night
8. Keep the nursing home as brightly lit as possible during the day
9. Match room-mates on basis of night-time as well as daytime behaviors and routines
10. Encourage exercise (appropriate to the patient's level of function)
11. Keep bedtime routines similar to prior routines at home whenever possible

day and during the night when compared with mild–moderately demented patients (Ancoli-Israel, Klauber et al., 1996). Systematic observations of sleep and wakefulness in a nursing home population also yielded similar results (Bliwise, Bevier, Bliwise, Edgar, & Dement, 1990).

A 1996 study explored the differences in profiles of alertness and sleepiness between severely and mild–moderately demented patients (Pat-Horenczyk, Jones, Martin, & Ancoli-Israel, 1996). Patients with mild–moderate dementia showed more alertness during the night, while patients with severe dementia showed more sleepiness during the day.

A multidimensional scaling analysis performed on the percentage sleep for each hour in severely demented patients and in mild–moderately demented patients suggested that in the mild–moderate dementia group, there was greater similarity in the level of sleep/wake between the daytime hours, whereas in the night-time hours the amount of sleep/wake varied greatly from hour to hour. In the severe dementia group, sleep/wake was equally disturbed during both the day and night. The authors concluded that sleep/wake patterns in severe dementia and in mild–moderate dementia were mainly different in the daytime hours. Mild–moderately demented patients had disturbed night-time sleep (sleep fragmentation), whereas the severely demented patients had both day and night disturbances (wake fragmentation during the day and sleep fragmentation during the night).

7.14.5 SUMMARY

In summary, sleep does change with age. Subjective complaints and objective measurements of sleep indicate an increase of sleep and wakefulness disturbances with old age. In general, elderly people sleep less deeply, have more fragmented sleep and tend to wake up earlier than younger adults. A central and controversial question is whether these changes constitute a decreased need for sleep with advanced age or whether it is the ability to sleep that diminishes with age.

Some of the changes in sleep are secondary to circadian rhythm changes. The circadian rhythm naturally advances a few hours with age, so older people may feel sleepy earlier in the evening and wake up earlier in the morning. There is also a high prevalence of sleep disorders, such as SDB and periodic limb movements in sleep, which contribute to sleep disruption. These disruptions in sleep lead to daytime sleepiness which has been objectively documented.

As mentioned, older people have a shorter sleep-onset latency on MSLT than younger adults, indicating more daytime drowsiness. Daytime drowsiness is caused by sleeplessness at night. This increase in daytime sleepiness seen in the elderly has been interpreted as support of the notion that it is the ability to sleep that changes with age and not the need for sleep. If the actual need for sleep decreased, there would be no daytime sleepiness. The fact that healthy elderly have normal sleep and that sleep complaints are associated with medical illness also supports the notion that it is the ability to sleep that decreases with age, rather than the need to sleep.

When evaluating an older person's sleep complaints, it is imperative to consider primary causes of sleep disturbances including medications, illness, depression, circadian rhythm changes, and sleep disorders. It is also important to remember that sleep of the elderly can be improved. Physical activity, natural light and sticking to a regular sleep/wake schedule may improve sleep and help to reset or stabilize the circadian clock. Not sleeping well at night and then napping during the day can cause a disturbed sleep/wake cycle.

Therefore, no matter what the age of the individual, a careful diagnosis needs to be made based on normal changes in sleep and on the complaints and history of that patient. Once the proper diagnosis is made, any sleep problem, regardless of the age of the individual, can be treated.

In conclusion, aging by itself does not cause sleep problems. Older adults do not need less sleep although sleep patterns do change with age. Rather, it is the ability to sleep that changes with age.

7.15.1 INTRODUCTION

7.15.1.1 Overview of Chapter

Adults with intellectual disabilities have needs for lifetime support and may require personal care, long-term health and mental health care, economic support, and social and housing services. The most consistent source of this care and support is the family. Nearly 80% of adults with intellectual disabilities live with their families (Fujiura, 1996). Although the likelihood of placement out of the home increases with age, family care still predominates for older adults with intellectual disabilities, at least while the parents are still alive (Meyers, Borthwick, & Eyman, 1985).

This chapter examines later-life caregiving for adults with intellectual disabilities from a life-course perspective that takes into account the social trends and changes in service patterns that effect these families. Older families have experienced pervasive changes in the context of caregiving. This life-course perspective aids in understanding their attitudes towards caregiving and their interface with the service system. The term "caregiving" includes both meeting socioemotional and instrumental needs. While we most often think of caregiving as unidirectional, in the case of older families caregiving can also be bidirectional encompassing support provided by the adult with intellectual disabilities to parents who are aging.

The introduction will present the sociodemographic trends affecting family caregiving. Subsequent sections will include: (i) description of life expectancy, demographic trends, and age-related changes for adults with intellectual disabilities; (ii) trends in services and supports and model of community inclusion; (iii) family caregiving across the life-course for mothers, fathers, and siblings and for various culturally diverse groups; (iv) support interventions that help adults with intellectual disabilities and their families cope with later-life transitions, including planning for the future; and (v) future research agenda.

7.15.1.2 Context of Family Caregiving

In the USA, the composition and structure of families have undergone major transformations since the 1950s that have changed families' abilities to provide care for dependent adults with disabilities. The traditional nuclear family consisting of a father who works out of the home and a mother at home providing care is in the minority. Rather, we see an increase in dual-income, single-parent, and step-families. We also see growing numbers of minority families and families living in poverty. At the same time increases in life expectancy extend the number of years for which families provide care for other members.

Increased life expectancy and lower fertility rates have contributed to the "aging" of the US population, with the median age rising from 28 years in 1970 to 33 in 1990. In 1950 the average life-course for persons born that year was 68 years. By 1990, average life expectancy had reached 78.8 years for women and 71.9 years for men. Projections are that average life expectancy will rise to 78 years by 2005 (US Bureau of the Census, 1992f). The percentage of adults aged 60 years and older is expected to increase from 17% of the US population in 1990 to 25% by the year 2030. The increase will be most dramatic for the oldest-old, with those over age 85 years projected to increase their numbers from 3.1 million in 1990 to 8 million by the year 2030 (US Bureau of the Census, 1992c). This growth of the elderly population will have a major impact on caregiving responsibilities within families across multiple generations as persons may need to provide care for parents, grandparents, and potentially, great-grandparents. This trend coupled with lower fertility rates, which have dropped from 3.6 children during the "Baby Boom Period" (1952–1964) to 1.8 in 1988, results in more demands for caregiving in later life and fewer siblings and children from which to draw support.

With an increasing number of single women bearing children, rising divorce rates, and higher life expectancy for women (Rossi, 1987), there has been a large increase in single parent households. Between 1970 and 1990 the percentage of US households with children under 18 years old headed by a single parent increased from 10% to 30%. This rise in single family households is most marked among African-American households, where by 1990 61% comprised single-parent households (US Bureau of the Census, 1992d).

Labor rate participation among women with children has increased in the last two decades. From 1975 to 1990 the percentage of married women with children under the age of 6 years who worked in paid employment increased from 37% to 59%. Across all ages 57% of married women and 68% of single women are in the workforce (US Bureau of the Census, 1992a). Hence, while the responsibilities of families across generations continue to increase, both the extent to which families can draw upon other family members for support and the time available for women caregivers has decreased. Furthermore, increased economic pressures on families have contributed to stress on caregivers. The economic situation has worsened for lower-income families, as the gap between the rich and poor has widened. As of 1990 13.5% of families in the USA were below the poverty level (US Bureau of the Census, 1992b).

There has been a rapid growth rate among racial/ethnic minority groups in the USA. Between 1980 and 1990 the growth rate was 108% for Asians, 53% for Hispanics, 38% for Native Americans, 13% for African-Americans, and only 6% for white non-Hispanics (Braddock, 1991). It is estimated that by the year 2050 the non-Hispanic white population will decline to only 53% of the US population (US Bureau of the Census, 1992e). Hence, any analysis of the caregiving experience for family members with intellectual disabilities needs to take into account differences among families attributed to cultural diversity and diverse family structures.

7.15.2 AGING IN ADULTS WITH INTELLECTUAL DISABILITIES

7.15.2.1 Life Expectancy and Demographic Trends

7.15.2.1.1 Growing numbers of older adults with intellectual disabilities

Intellectual disabilities (commonly referred to as mental retardation in the USA) is defined by the American Association on Mental Retardation as significant subaverage general intellectual functioning existing concurrently with deficits in adaptive behaviors which are first manifested before the age of 18 years (Luckasson et al., 1993). About 20% of adults with intellectual disabilities require assistance in performing basic activities of daily living such as dressing and bathing (Center for Vulnerable Populations, 1993). Generally, persons with intellectual disabilities show stability in their functional and cognitive levels in adulthood, at least prior to age-related changes in later life (Eyman & Widaman, 1987). Estimates of the prevalence of intellectual disabilities range from 1% to 3% of the population, depending on whether persons with mild forms of intellectual disabilities are included. The prevalence appears to be similar across ages, with some decrease at the oldest ages. However, the proportion of persons with intellectual disabilities who show up in the service system varies, with the greatest proportion served in the school age (McClaren & Bryson, 1987). It has been estimated that as many as 40% of adults with intellectual disabilities are not known to the service system (Krauss, 1986).

The number of older people with intellectual disabilities is not known. However, it is estimated that the age distribution will mirror that of the general population, with a large growth in the elderly population. Using the prevalence rate of 1.2% (which includes both persons known and not known to the service system) recommended by McClaren and Bryson (1987) it is estimated that the number of adults with intellectual disabilities aged 60 years and over in the US will increase from 503 000 in 1990 to 1 065 000 in 2030.

7.15.2.1.2 Increased life expectancy

Historically, persons with intellectual disabilities have had short life-spans, with many dying in childhood (Eyman & Borthwick-Duffy, 1994). With improved medical interventions, better social conditions, and technological advances, the life expectancy of adults with intellectual disabilities has improved substantially. From 1931 to 1980 the life expectancy increased from 15 years for males and 22 years for females to 58 years and 60 years, respectively, in 1976–1980 (Carter & Jancar, 1983). The increase had been most marked for persons with Down syndrome. Their life expectancy has risen from 9 years in 1929 to 55 years by 1995 (Adlin, 1993). Adults with milder forms of intellectual disabilities who do not have other physical disabilities, generally have the same life-span as the general population (Eyman & Borthwick-Duffy, 1994). Exceptions are people with Down syndrome, cerebral palsy, and more severe forms of intellectual disabilities (Heller, 1997).

With the longer life-spans of both adults with intellectual disabilities and their relatives, the period of family caregiving is much longer than in the past. Also, the likelihood that adult children with intellectual disabilities will outlive their parents has increased, with most expected to outlive their parents by several decades.

7.15.2.2 Age-related Changes

7.15.2.2.1 Biological and psychosocial changes

It is commonly assumed that persons with intellectual disabilities experience precocious aging. Yet, the research indicates that this phenomenon is only true for some subgroups, such as those with Down syndrome, severe levels of cognitive disability, cerebral palsy, or epilepsy (Heller, 1997). Persons with milder forms of intellectual disabilities experience age-related problems similar to those of the general population. In a large population study of adults with intellectual disabilities in Great Britain (Hogg & Moss, 1993) chronic diseases increased from age 50 years on, hearing loss from age 60 on, and mobility loss and incontinence from age 70 on. When compared with a general elderly group, older adults (age 50 years and over) with moderate to severe intellectual disabilities had a higher rate of incontinence and obesity, and a lower rate of angina (Wilkin, Durie, Wade, Jolley, & Stout, 1984). Cross-sectional analyses of age-related differences among adults with intellectual disabilities generally find a bias due to differential mortality, with those surviving to old age generally having better health and higher levels of cognitive ability.

Generally, studies that have examined adaptive behavior, maladaptive behavior, and cognitive changes among adults with intellectual disabilities have found few age-related changes, when persons with Down syndrome were not included. Researchers have noted some gradual decline in overall intellectual functioning after the age of 65 years (Fisher & Zeaman, 1970; Walz, Harper, & Wilson, 1986).

Losses in social support and in physical functioning can contribute to psychiatric disorders for older adults with intellectual disabilities. Often issues of death and bereavement are not adequately addressed in this population. Also, psychiatric problems tend to be underdiagnosed among adults with intellectual disabilities (Patel, Goldberg, & Moss, 1993). After thoroughly screening a community population of older adults with intellectual disabilities (age 50 and over) Patel et al. (1993) diagnosed 11.4% of the sample as having a psychiatric disorder (mostly depression and anxiety) other than dementia. Only one third of these cases had been identified and treated for their disorder.

7.15.2.2.2 Earlier aging for some conditions

Earlier aging occurs for persons with Down syndrome and to some extent for persons with cerebral palsy and epilepsy. Often, age-related changes can be due to secondary conditions related to the disability. For example, long-term use of antiseizure medication appears to be associated with an increased risk of osteoporosis and fractures (Adlin, 1993). For adults with Down syndrome there is a higher prevalence of Alzheimer's disease at a younger age (starting with age 50 years), which also is related to decrements in adaptive behaviors and increased maladaptive behavior (Janicki, Heller, Seltzer, & Hogg, 1996). Persons with Down syndrome also experience other age-related health problems, including hypothyroidism, depression, and sleep apnea, which can mimic the symptoms of dementia (Adlin, 1993).

For adults with cerebral palsy, aging-related changes have been noted starting in the 40s. These include decreased muscle strength and mobility, problems with choking and swallowing, increased pain, and incontinence (Turk, Overeynder, & Janicki, 1995). It is not uncommon for persons with cerebral palsy to begin using a wheelchair in middle age, as walking becomes more difficult and fatigue is greater.

7.15.3 TRENDS IN SERVICES AND SUPPORTS

7.15.3.1 Models of Care and Residential Services

7.15.3.1.1 Growth of community vs. institutional programs

Older adults with intellectual disabilities and their families have witnessed major changes in the service system and in ideologies concerning best models of care and support. For over 120 years from 1850 to the 1970s the dominant paradigm of care for persons with intellectual disabilities emphasized institutionalization and segregation. They often were sent to far-away institutions and special schools. Medical professionals dominated and made most of the decisions regarding the medical and educational needs of the children. Many older parents recall their early encounters with physicians who told them that their child had to be institutionalized because of the intellectual disabilities diagnosis. During this era there were no publicly funded schools or day/vocational programs for children with intellectual disabilities and few supports for families who chose to maintain their relative at home. At the height of this "institutional" era in 1967 there were 194 650 children and adults with intellectual disabilities and developmental disabilities in institutions (Braddock, Hemp, Bachelder, & Fujiura, 1995).

Beginning in the 1950s parents began to challenge the institutional and segregated model. They created the national Association for Retarded Children (renamed The Arc) which is the fourteenth-largest nonprofit organization in the USA. Largely through the efforts of the parent movement and class action lawsuits, legislation was passed that provided public education services to children with disabilities, including Public Law 194-142 in 1975, which guaranteed free and appropriate public education for all children with disabilities aged 3 to 21 years. Although older adults with disabilities were not able to benefit directly from this law as they already were adults by the time this law was passed, they have benefitted from its influence on families' expectations and advocacy for adult services.

The period 1976–1986 has been characterized as one of deinstitutionalization and community development (Bradley & Knoll, 1990). This phase emphasized a shift from the medical model to the developmental model, with specialized services that trained people for integration into more independent settings. During this era there were efforts to phase down or close large institutions and to develop other residential programs in the community, including large group homes and living centers. Concurrently, there was a major growth in schools, sheltered workshops, and activity centers located within the community. The model implied that there was a "continuum of services" and that persons needed to learn skills to advance to the less restrictive level of care. A major problem with this model was that without appropriate environmental supports most adults never "progressed" to the next level.

The 1990s model which is being promulgated is one of community membership. This approach emphasizes individualized functional supports to enhance community inclusion and quality of life. Services are being reconfigured to incorporate more emphasis on the role of informal family and community supports, consumer control, and individualized approaches. Rather than emphasizing skill development learned in specialized settings, its emphasis is on providing supports to individuals with disabilities in the natural setting, such as in supported employment, supported living arrangements, assistive technology and environmental accommodations, and family supports. There has also been an emphasis on civil rights for people with disabilities. This has been particularly evident with the passage of the Americans with Disabilities Act of 1990 (PL 101-336), which prohibits discrimination against individuals with disabilities in enjoyment of goods, services, privileges, and public accommodation.

Since the peak era of institutionalization there has been a steady decline in the institutional population and a concomitant increase in community-based services. By 1992 the majority of persons with intellectual disabilities living in out-of-home placements were living in small versus larger residences (170 077 vs. 165 119) (Braddock et al., 1995). However, older adults are much more likely than younger persons to be living in larger residential settings (Heller, 1997). Furthermore, there have also been federally mandated transfers of adults with developmental disabilities out of nursing homes and into other community-based settings. The Nursing Home Reform Act, part of the Omnibus Budget Reconciliation Act of 1987, required that all residents with a developmental disability who did not have skilled nursing medical needs move out, unless they had lived in the nursing home for over 30 months and chose to stay there. Between 1988 and 1992 their numbers decreased from 50 606 to 41 429 (Braddock et al., 1995).

7.15.3.1.2 Waiting lists and unmet needs

With the massive phase down of persons with intellectual disabilities from institutions and nursing homes and the lack of sufficient growth of alternative options to meet growing needs for residential supports, there has been a concomitant increase in the waiting list for residential services. A national survey indicated that in 1992, 60 876 people with developmental disabilities were on waiting lists for residential services in 37 states (Hayden, 1992). In addition, there is a big demand for day programs, with the same survey indicating that over 35 095 adults with developmental disabilities were on waiting lists for day habilitation or vocational services.

Services tend to go to persons already in the service system. Often, the older families who have chosen to rear their children at home and who have continued to care for them into adulthood face long waiting lists when they begin to look for placements. Furthermore, the actual demand is probably underestimated by waiting lists, as many families are unknown to the system (Krauss, 1986) and many other families, especially older ones, are wary of formal services. Some of this can be attributed to their earlier experiences with poor or nonexistent services when their children were younger. Other families may be unaware of the available options. Several outreach studies have identified numerous families who previously had not received any formal day or residential services for their relative with intellectual disabilities (e.g., Smith, Fullmer, & Tobin, 1994; Wood & Skiles, 1992). In a 1992 study of families age 55 and over caring for children with intellectual disabilities, only 33% had any involvement with any provider agencies (Wood & Skiles, 1992).

7.15.3.2 Community Inclusion Models for Older Adults

Paralleling the changing concepts of care for persons with intellectual disabilities, models for community inclusion of older adults with intellectual disabilities also have been rapidly changing. In the late 1970s through the 1980s there was a growing recognition that the population of older adults with intellectual disabilities was increasing and that they may require specialized services targeted to them. This segregated model focused on special senior programs within workshops or residential facilities. These programs were often modeled after seniors programs in the general population. The next phase emphasized community inclusion, either in terms of being integrated into the generic aging services programs or in terms of being included in the general community.

7.15.3.2.1 Integration into the aging service network

Integration into the aging service network has occurred on many levels: (i) federal and statewide legislation and memorandums of agreements in which the aging and disability networks agree to work together, (ii) integration of adults with intellectual disabilities into seniors residential and day programs, and (iii) combined outreach to families.

Amendments to the Developmental Disabilities Assistance and Bill of Rights Act (PL 100-142) and the Older American Act (PL 89-73) in the USA have fostered collaborative program planning and development across the aging and intellectual disabilities service systems. Examples of such programs include senior center/senior companion programs, nutrition programs, and senior adult day programs. The senior companion programs, in which staff, volunteers, or friends involve adults with intellectual disabilities in these various senior services and in other community activities has generally documented improvements in the social integration and self-esteem of participants (Roberts, 1990).

Outreach to older adults and their families has been successfully implemented through collaboration of both networks. For example, the Caregiver Resource Program in New York has outreached to numerous older family caregivers of adults with intellectual disabilities through the Area Agencies on Aging (Janicki, 1996). Many of the families who had never been linked to any formal services were more responsive to the aging network than to the intellectual disabilities service network. This could be attributed to lack of knowledge, previous negative experiences, or to feelings that their needs were primarily related to aging-related changes rather than to their child's intellectual disabilities.

7.15.3.2.2 Inclusion into the general community

Fitting in with the emerging model of community membership, other approaches to services and supports to older adults with intellectual disabilities focus on individualized programs that offer a wide variety of options. These can include making use of intellectual disabilities services, aging services, or services and activities offered to the general community. Examples of innovative programs using such an approach are the Community Entry Project (Blaney, 1995) and the Person-Centered Later Life Planning Project (Heller, Sterns, Sutton, & Factor, 1996). The Community Entry Project worked with older adults in creating a circle of support, which could include parents, guardians, staff members, friends, and service coordinators. This group then helped the individual connect with community activities in natural settings, such as YMCA programs, church groups, volunteer activities, and art classes. Another example, the Person-Centered Later Life Planning Project has developed a training program which helps older adults with intellectual disabilities become more informed about community options and better able to make choices and goals regarding their future. Also, it provides opportunities for greater choice-making through training of staff and families. Research examining the effectiveness of this program has indicated its success in increasing participants' knowledge of later-life options and increasing participation in leisure activities for participants living at home. Additionally, the training resulted in greater consideration of the preferences of older adults with intellectual disabilities in the actual goals developed in planning meetings with staff and families.

With the emerging models of community membership there is a greater emphasis on involving natural supports, including family and friends, than in previous segregated models that emphasized professional involvement. Hence, families are expected to be integrally involved in developing service plans, providing support, and in some cases directing services. This chapter more specifically discusses family support programs and new models of family consumer-direction in a later section.

In summary, the first three sections of this chapter provide a general overview of the historical changes that have effected the context of family caregiving for adults with intellectual disabilities. These have included changes in demographics and in service ideologies and trends. In addition, this chapter summarizes major biological and social psychological changes that adults with intellectual disabilities face as they age. These changes along with age-related changes of family caregivers affect their caregiving experience.

7.15.4 FAMILY CAREGIVING ACROSS THE LIFE-SPAN

7.15.4.1 Changes across the Life-span

7.15.4.1.1 Theories of family caregiving over the life-span

A life-span perspective on family caregiving recognizes that caregiving can span many decades and is usually a lifetime commitment for families of adults with intellectual disabilities. Unfortunately, the research examining caregiving across the life-span is sparse. Rather, most studies focus on particular ages, with the vast majority focusing on childhood. However, there have been studies focusing on older caregivers. In examining caregiving across the life-span, the terminology differs. Studies focusing on children typically refer to the "parenting" role; whereas studies focusing on adults refer to the "caregiving" role. A few studies have begun to examine caregiving reciprocity as adults with intellectual disabilities begin to serve caregiving roles for older parents (Heller & Factor, 1993a).

Over time, caregiving roles, stressors, and rewards are likely to have both stable and dynamic aspects. In examining the effects of caregiving over time, researchers need to take into account developmental transitions occurring for the person with a disability and the caregiver, changes in the availability of services and supports, and changes in societal attitudes towards the individual with a disability. Another important dimension could be the changing nature of societal expectations regarding caregiving and opportunities for fulfillment of other life roles. Several theories from the gerontological and intellectual disabilities literature address some of these dimensions in understanding the dynamic nature of caregiving over time.

Two contrasting theories emanating from the gerontological literature offer a framework for understanding family adaptation over the life-span. The "wear and tear" hypothesis predicts that the constant caregiving demands and accumulation of stressors will deplete the caregiver's physical and emotional resources (Johnson & Catalano, 1983). Several cross-sectional studies of caregivers of aging relatives have provided some support for this theory (e.g., Morycz, 1985; Zarit, Reever, & Bach-Peterson, 1980).

On the other hand, the "adaptational" hypothesis suggests that, with experience, caregiving becomes easier (Townsend, Noelker, Deimling, & Bass, 1989). The assumption is that when caregiving is a new role it is most stressful and that over time families learn to cope. Several longitudinal studies of caregiving for elderly relatives have reported less caregiving burden and depression over time despite deterioration in the condition of the elderly relative (Townsend et al., 1989; Zarit, Todd, & Zarit, 1986).

7.15.4.1.2 Findings on families of adults with intellectual disabilities

In the intellectual disabilities literature there has been support for both hypotheses, with reports of increases in both positive and negative adaptations over time and with much variability in family adaptations over time. The theories and research on intellectual disabilities also examine adaptation to caregiving from a developmental perspective that takes into account the normative life stage tasks faced by families at different life phases. Birenbaum (1971) and Farber (1975) have addressed the degree to which caregiving is normative vs. non-normative as the child with intellectual disabilities grows older. They suggest that as the child moves towards adulthood, caregiving becomes less normative, particularly if the child is still highly dependent on the parents. Birenbaum has noted that as the child gets older the rights and obligations of typical parenthood become more taxing and more divergent from normative roles. Similarly, Farber discusses the notion of "arrest in the life cycle," referring to the fact that as the child reaches adolescence and adulthood, the parents often are still involved in parenting tasks more typical in families with younger children. As children with intellectual disabilities become adults, most continue to live with parents, unlike what occurs in most families. Hence, parents of adults with intellectual disabilities are much less likely to experience an empty nest.

In addition to fulfilling roles that are less normative with age, parents of adults vs. children with intellectual disabilities are less likely to receive as much formal service support for their child. Suelzle and Keenan (1981) reported that families of adults were more stressed than families of children with intellectual disabilities. They attributed this greater stress to the lack of adult services. While there is US federal legislation mandating educational services for all children with disabilities, there are no mandates for educational, vocational, or residential services for adults with disabilities. Hence, in some families, the parents are the sole providers for their adult child with intellectual disabilities who may not be receiving any services or who may be on a waiting list for services. Furthermore, many of these adults lack friends and rely on their parents to meet their social recreational needs (Heller & Factor, 1988).

In discussing life-time accommodations to caregiving of a child with intellectual disabilities, Todd and Shearn (1996) discuss the meaning that parents give to the caregiving experience and its effect on their identity. They note that socialization into the parental role continues over the life course and entails a series of incremental changes and re-evaluations. They found different reactions of families depending on their interpretations of past experiences, anticipated futures, and personal aspirations. In their ethnographic study of 17 parents of adults with intellectual disabilities in Wales, Todd and Shearn describe how some of these older parents come to experience heightened stress as a consequence of their inability to end their parental responsibilities for their child with a disability. "In the beginning you know that you're going to be responsible for the rest of your life in one way or another, but you never really know in what way. It's like you just roll up your sleeves and get stuck in" (p. 8). Parents reported that adolescence was a turning point as their normalizing strategies were becoming less successful when the character of their own lives departed more from that of their peers. In the process of comparing themselves to others, caregivers (mothers in most cases) who had given up careers and other pursuits to care for their child with a disability, experienced greater discrepancy from the lives of their peers as their children got older.

On the other hand, there is also evidence supporting the adaptational hypothesis that, with time, caregiving for family members becomes less stressful and more rewarding. In a large study of 450 mothers aged 55 and over caring for an adult child with intellectual disabilities Seltzer and Krauss (1989) found, on average, favorable well-being. A higher proportion of these mothers rated their physical health as good or excellent (78%) than did a national probability sample of women their age (60%; Sweet & Bumpass, 1987) and they were less stressed than in other samples of caregivers of elderly relatives (e.g., Zarit et al., 1980) or relatives with intellectual disabilities (e.g., Friedrich, Greenberg, & Crnic, 1983).

In one of the few studies to examine family adjustment throughout the life-span Heller, Rowitz, and Farber (1992) compared 489 family caregivers grouped into five age phases based on the age of the person with intellectual disabilities: preschooler, young child, adolescent, young adult, and older adult. They found that perceived burden was lowest for caregivers of the youngest (under six years of age) and oldest (30 years and older) members with intellectual disabilities. They suggested that perhaps at this stage there is greater acceptance of the family member and greater reciprocity in caregiving as the child with intellectual disabilities takes on caregiving roles with aging parents. Seltzer and Ryff (1994) also suggest that for some mothers the experience of rasing a child with intellectual disabilities might lead to the development of new capacities and strengths that foster adaptational responses. Although the Heller et al. (1992) study was limited by its cross-sectional design and potential cohort effects, parents' retrospective reports further supported the notion of adaptational responses over the years. Families reported how over the years it became easier to adjust to the routines; they became more knowledgable about what was expected of them, and they understood their child better. Another frequent theme was that parents grew to love and appreciate their child more. These affectional bonds between the parent and child can nurture both the parent and the child (Seltzer & Ryff, 1994).

Todd and Shearn (1996) note that some parents make a career of parenting and redefine the centrality of parenting as the major line of activity open to them, beginning to interpret it more positively. Over time, parenting became a stronger source of self meaning and purpose.

While most of the research on adult children with intellectual disabilities has portrayed them as sources of burden to their primary caregiver, studies are beginning to document the positive contributions they can make to their families. Heller and Factor's (1988) study of 100 parents caring for adults with intellectual disabilities (aged 30 years and older) found that these children were an important source of support for them. In addition to providing meaning to their lives, many families reported that their child did chores for them, contributed financially through their Social Security Income, and kept them from feeling lonely. In a study of 85 family caregivers of adults (aged 30 years and over) that specifically addressed caregiving reciprocity, Heller and Factor (1993b) also found that adult children with intellectual disabilities provided considerable companionship support to their parents and help with household chores. Support from the child with intellectual disabilities was a key factor predicting parents' degree of perceived caregiving satisfaction and caregiving burden. Parents who received support from their adult child with intellectual disabilities experienced greater caregiving satisfaction and less caregiving burden. This reciprocal support may be particularly important as parents experience frailty due to aging or widowhood.

Both the "wear-and-tear" and "adaptational" hypotheses assume a linear relationship between time and caregiver well-being. Neither account for periodic variations in levels of stress as families experience major transitions, such as when the child enters or completes school or when the child moves out of the family home. Often the least stressful times are periods of stability in family roles (Wikler, 1986). These hypotheses also do not account for variability in characteristics of the child and in the family's coping and support resources.

7.15.4.1.3 Predictors of caregiver well-being in later life

Both characteristics of the child and of the family and coping and support resources can explain the wide variability in responses of families to caring for a child with intellectual disabilities over the lifespan. The major risk factors for stressful reactions in later life are having a child with more severe intellectual disabilities and more maladaptive behaviors (Heller & Factor, 1993b; Pruchno, Patrick, & Burant, in press).

The extent that formal services can reduce caregiver burden and increase families' ability to maintain caregiving in the home is unclear. However, in their two year longitudinal study of parents caring for adults with intellectual disabilities aged 30 years and over, increase in the number of perceived unmet formal needs was associated with increased caregiving burden and increased need for out-of-home placements (Heller & Factor, 1993b). However, greater use of services has not been associated with improved parental well-being. This chapter discusses the impact of family support services in greater detail in the section on "family support interventions and policies."

There is some evidence that informal support from family and friends can reduce burden (Heller & Factor, 1994; Seltzer & Krauss, 1989). In particular, a high level of sibling involvement with the adult child with retardation has been associated with positive maternal well-being. Seltzer, Begun, Seltzer, and Krauss (1991) found that when support was provided by the sibling to the adult child, mothers reported better health and life satisfaction than when mothers had no other children or received no such help from their other children. The critical variable was not the amount of support given to the mother, but the amount given to the adult child with a disability. They note that perhaps sibling involvement indicates potential continuity of family caregiving into the future.

7.15.4.2 Roles of Mother, Fathers, and Siblings

Much of the literature on family caregiving has focused on mothers, with little mention of the role of fathers or other siblings. Yet, each of the members' roles are interrelated and affect the ability of the family to cope with raising and caring for a child with intellectual disabilities.

7.15.4.2.1 Comparison of maternal and paternal caregiving

One of the most consistent findings in family research is that mothers are the primary caregivers across the lifespan (Hooyman & Gonyea, 1995). However, in the intellectual disabilities literature there have been only a few studies that compare the maternal and paternal roles and most of these studies have focused on families of young children. These studies have generally found that parental roles tend to be even more traditional in families that have a child with intellectual disabilities than in families that do not have a child with a disability. After the birth of a child with a disability, mothers are much less likely to return to work than are other mothers. In a study of two-parent families in which the mother worked prior to the birth of a child with a disability, Mardiros (1985) found that only 8% returned to work afterwards. Fathers of young children with a disability tend to assume less task involvement with the care of their child than do the other fathers. Willoughby and Glidden (1995) found that among parents of children with intellectual disabilities the only tasks in which fathers participated nearly equally with the mothers were those of play and helping with activities.

Several studies have found higher subjective caregiving burden among mothers than fathers of children (Beckman, 1991; Kazak, 1987) and of young adults with a disability (Hallum & Krumboltz, 1993), although some have found little differences in burden (Bruce & Schultz, 1994; Essex et al., 1992; Friedrich et al., 1983), or only in some dimensions of burden (e.g., pessimism) (Rousey, Best, & Blacher, 1992). In a cross-sectional study of 113 two-parent families of children and adults with intellectual disabilities, Heller, Hsieh, and Rowitz (in press) found that mothers spend more time in caregiving tasks for their child, offer more types of support, and perceive more caregiving burden than do fathers. These gender differences persist from childhood into adulthood and whether or not the child continues to reside in the family home.

In addition to the explanation that women have been socialized to play nurturant roles, another explanation for these gender differences in caregiving could be attributed to women having fewer competing roles and time demands, enabling more time to provide care. However, in a study of caregivers for elderly relatives (Stoller, 1983) employment has been shown to affect men's assistance to aging parents, but not women's care to parents. Among older fathers of children with intellectual disabilities, the father's retirement has not been related to increased involvement in the care of the child (Essex, Seltzer, & Krauss, 1992). Even when the mother is employed, men are not more likely to help with the household tasks or with care for the child with intellectual disabilities (Heller et al., in press; Marcenko & Meyers, 1991; Willoughby & Glidden, 1995). Also, women's employment does not seem to be related to the amount or type of help she provides her child with a disability. This could be one explanation for women reducing or giving up paid employment after the birth of a child with a disability. Both Heller et al. (in press) and Todd and Shearn (1996) have noted that many older mothers report that having a child with a disability hurt their job opportunities.

In examining predictors of maternal and paternal involvement and perceived burden, Heller et al. (in press) found that both mothers and fathers provided less support to the adult vs. the child with a disability and less to offspring who lived out of the home. Both mothers and fathers perceived less caregiving burden when children remained in the home and adult offspring with a disability were placed out of the home. Hence, placement out of the home seemed to be associated with reduced burden for parents of adults, but not for parents of children. One reason could be that launching out of the home is a normative function for adults, but not for children.

Given that mothers spend more time caring for the child having a disability than do the fathers, they appear to be more affected by the extent of the child's disability. Hence, in the Heller et al. (in press) study both the child's maladaptive behavior and physical health were related to higher perceived caregiving burden for the mother but not for the father. Also, mothers and fathers were differentially affected by their other role commitments and by the role commitments of their spouses. Mothers perceived the least burden when they were involved in organizational activities and when their husbands worked fewer hours. On the other hand, for fathers, neither their nor their wife's involvement in other roles had much effect on their perceived caregiving burden. However, given the correlational nature of the research it is also possible that fathers work more when their wives are more stressed either to provide better for the family or to avoid stressful family life (Farber, 1959).

Although family caregiving is predominantly a woman's task, fathers play a significant role in providing support. This support continues throughout the life-span, whether the offspring with a disability lives at home or out of the home. Often, fathers play an increasingly large role as their wife dies or becomes incapacitated, assuming the role of primary caregiver, previously held by the mother. Gordon, Seltzer, and Krauss (1996) found that upon the mother's death very few fathers sought out-of-home placement for their child with intellectual disabilities. These authors suggest that it is easier for fathers to move into the role of primary caregiver than to adjust to the empty nest after placement. Placement of their child also may remind fathers of their own mortality.

7.15.4.2.2 Sibling caregiver roles

Siblings provide the most durable relationships for adults with intellectual disabilities. They often share both common genes and the common experiences of growing up in the same family. Relationships among siblings without a disability are most typically egalitarian (Baskett & Johnson, 1982) and often intimate. The long-term impact of having a sibling with intellectual disabilities has been rarely studied.

There has been a large body of literature on the social and psychological effects of having a sibling with intellectual disabilities on children (Lobato, 1983). Generally, the research indicates that some siblings are at risk for greater emotional problems than other children. These siblings are more likely to have increased caregiving responsibilities, lower socioeconomic status, and anxiety or guilt surrounding the sibling with a disability (Begun, 1989). McHale and Gamble (1989) found that siblings of children with intellectual disabilities took on more household and caregiving responsibilities, but had similar well-being to that of siblings without a brother or sister with a disability. Other studies have noted the positive and valued aspects of having a sibling with a disability (Cleveland & Miller, 1977; Wilson, Blacher, & Baker, 1989). These studies have attributed the positive adjustment of siblings to parental attitudes and behaviors that fostered a family environment attentive to the needs of all members and that did not overly focus on the child with a disability.

There is some evidence that adult siblings of persons with intellectual disabilities continue to maintain involvement with their brother or sister with intellectual disabilities into adulthood and throughout the lifespan. Generally, these studies have found that these adult sibling relationships differ from those of other sibling dyads in that the relationships are less egalitarian and less intimate. Zetlin's (1986) study of sibling relationships of 35 adults with intellectual disabilities found that the relationship was hierarchical, with the disabled sibling being more emotionally dependent on the nondisabled sibling. Two larger studies of siblings of adolescents and adults (Heller, 1994; Seltzer et al., 1991) found that the nondisabled sibling performed nearly twice as many support functions for the other siblings than they received back from them. Heller (1994) also compared sibling involvement across ages. Among 175 siblings aged 11 years and older of siblings with moderate to profound intellectual disabilities, adults were more likely than adolescents to spend time helping their relative and to perform more support functions. This was despite the fact that adults were more likely than adolescents to be living out of the family home.

In examining the nature of supports provided by 326 siblings of adults with intellectual disabilities, Krauss (1993) found that these siblings were more likely to provide affective support (86%) than instrumental support (25%) to their sibling with a disability. The factors determining support functions provided differed for the two types of support. For affective support the key factor was past interpersonal climate of the family of origin, including greater cohesion and expressiveness; for instrumental support the key factor was the objective need for support, such as when the mother was older and widowed. The sibling was most likely to provide support when the sibling with a disability had less severe intellectual disabilities and the needs were seen as less demanding.

Several researchers have noted the positive but not intimate relationship between siblings with intellectual disabilities and their nondisabled siblings (Begun, 1989). Begun notes that these relationships were less intimate because it is more difficult to interact intimately with persons having limited language and social communication skills than it is to interact with nondisabled siblings. However, when the functioning level of the sibling with intellectual disabilities was higher the sibling relationship more closely resembled normative sibling relationships.

As parents can no longer care for their child with intellectual disabilities either due to frailty or death, other siblings begin to take on the role of primary caregiver. Griffiths and Unger (1994) reported that nearly 44% of 41 adult siblings interviewed were willing to take on future caregiving responsibilities if needed. Willingness to assume responsibility depended on the degree to which parents desired it and family communication was positive. In the Krauss, Seltzer, Gordon, and Friedman (1996) study of 140 adult siblings, 36% intended to coreside with their bother or sister with intellectual disabilities. These siblings were more likely to be sisters, as is typical of caregiving across disabilities (Hooyman & Gonyea, 1995). They also had siblings with less dependency needs and had engaged in more joint activities with their sibling. Hence, a sibling was more willing to take on the responsibility if the task did not seem too demanding. Furthermore, they were more likely to anticipate coresidence if their mother was already in poor health, making the transfer of responsibility more eminent.

Despite the fact that siblings are often expected to take on the primary caregiving role, often they are not consulted about future plans. For example, in the Krauss et al. (1996) study, only half of the siblings who expected to coreside with their sibling had discussions with their parents regarding future plans for their brother or sister. One explanation for families' reluctance to discuss these future plans is ambivalence about wanting another sibling to take on the responsibility. As a mother in one of our studies noted "I just do not want to burden our daughter." Another mother noted "My daughter has offered to care for her, but I know she works and it would be difficult for her." Hence, many siblings assume caregiving upon the death of their parents without sufficient planning and information about the needs and preferences of their siblings and the support services available to them.

In an examination of actual placements over a 3 year period following the death of parents, Gordon et al. (1996) found that in nearly one-quarter of the 21 families the adult with intellectual disabilities moved in with his or her sibling. They found that even when the adult with intellectual disabilities moved into an out-of-home placement, there was considerable sibling involvement, with many taking on the roles of guardian and advocate. In some cases they assumed these roles out of a sense of obligation to the deceased parents, and in others they did so out of personal desires to help their sibling.

7.15.4.3 Future Planning and Placement

As family caregivers age they increasingly face the prospect that their child with intellectual disabilities will outlive them. With increased frailty it may also be more difficult for parents to provide care. While planning for the future is a task faced by all persons as they age, the need to plan for their child is particularly salient and often stressful for these parents. Key aspects which usually need to be addressed include future living arrangements, guardianship, and financial planning. However, many of these older adults have great difficulty making future plans as do older adults in general (Heller & Factor, 1994).

7.15.4.3.1 Residential plans

Several studies have noted that only between one-third and one-half of aging parents make concrete plans for the their relative's future living arrangements (Freedman, Krauss, & Seltzer, 1997; Heller & Factor, 1994; Roberto, 1988; Smith, Fullmer, & Tobin, 1994). Residential planning is one of the most anxiety-provoking aspects of future planning as it reminds families of their mortality and it can invoke unspoken concerns regarding family responsibility, separation, and independence (Freedman et al., 1997). Furthermore, parents who have cared for their child at home for decades may be reluctant to relinquish their role. Older families often report that providing care for their relative within the family home provides meaning to their lives. The launching stage is a transition point which can result in considerable family accommodations, disequilibrium, and decreased well-being (Seltzer, Krauss, Choi, & Hong, in press).

While many families do not make concrete plans for living arrangements, most have preferences regarding the type of care they would like, and most would like to have plans in place in their lifetime (Heller & Factor, 1991; Roberto, 1988). About half of the families prefer continued care with another family member, usually a sibling of the adult with intellectual disabilities, and the other half would like an out-of-home placement. However, when families do begin to consider residential programs, they face long waiting lists (Hayden, 1992) and have significant concerns about the quality of housing options. A common sentiment of these families is that staff could not possibly provide the same degree of caring and understanding that a parent could. As one parent commented "It would break our heart to place her; there is no place like home and your parents; they know what their child is like" (Heller & Factor, 1988, p. 40). Wood and Skiles (1992) have noted that the caregiver's reluctance to plan may reflect both limited awareness of services and actual gaps in the service system. Apprehension about the residential service system may be particularly strong for older parents who may have had negative experiences when their children were young and when adequate community services were nonexistent.

Lack of planning by families can lead to emergency placements, difficulties for other family members who suddenly assume responsibility for their relative upon the death or frailty of a parent, pressures on the service system, and major disruptions in the daily life of the adult with intellectual disabilities. Also, without planning and discussions with other family members it is not possible to consider the views and preferences of various family members. Many parents do not discuss future plans with other family members or with their son or daughter with intellectual disabilities (Heller & Factor, 1994; Smith & Tobin, 1989). In a study that interviewed adults with intellectual disabilities (Heller & Factor, 1993a), we found that nearly half of the adults aged 30 years and older wanted to move out of the family home either to gain more independence or to live with friends. Those who wanted to remain with families stressed the desire for stability or the reciprocal supports they provided to and received from parents.

7.15.4.3.2 Predictors and outcomes of placement

Generally the parents who are most likely to make residential plans are those of higher socioeconomic status (Heller & Factor, 1991). Freedman et al. (1997) differentiate short-term (wanting a change in settings in less than two years) from long-term planners and note that the short-term planners are more likely to have health problems, worries about the future, and lower sense of purpose than longer-term planners or persons who had not made plans. The long-term planners had the most positive well-being of all the groups. A three-year follow-up indicated that the short-term planners were more likely to have achieved out-of-home placements.

The variables predicting preferences for future out-of-home placement versus actual placements differ. Heller and Factor's (1993b) longitudinal study indicated that over a two year period the major predictors of both outcomes were high perceived unmet need for formal services. High maladaptive behavior was associated with desire for placement, but not with actual placement. Actual placement was related to parents' perceptions that caring for their relative would become more difficult and to having placed their relative on a waiting list for residential services. In a study spanning three years, Seltzer, Greenberg, Krauss, and

Hong (1997) similarly found that placement was most likely to occur when the mother was in poor health and had placed her child on a waiting list. This pattern is similar to the factors predicting nursing home placement for elderly persons (Colerick & George, 1986; Pruchno, Michaels, & Potashnik, 1990) with characteristics of the caregiver playing a larger role than characteristics of the care recipient.

In examining outcomes of placement, Seltzer et al. (1997) found that parents' level of perceived caregiving burden was lower after placement. Although nearly 94% of the mothers maintained at least weekly contact with their child and at least one-third of the mothers continued providing them with some care, the mother's level of perceived burden was lower. With placement the daily caregiving responsibilities were reduced. In addition to reducing burden, out-of-home placement prior to the death of either or both parents can result in better outcomes for the adult with intellectual disabilities, in contrast with placements made after parental death. Gordon et al. (1996) found that the latter placements often result in more disruption in lifestyle, including not only a change in residence but also a change in day program and social life. These findings point to the importance of planning in advance of major parental declines in health.

7.15.4.3.3 Legal and financial planning

Legal and financial planning are other challenges for families who want to assure financial resources for their relative with intellectual disabilities without jeopardizing government benefits and who want to obtain guardianship if their relative is incompetent. In the Heller and Factor (1991) study nearly two-thirds of families of adults aged 30 years and over had made financial plans and nearly one-quarter had made guardianship plans. As with planning for living arrangements, the extent that families make plans is tied to their socioeconomic status. Certainly, families who are wealthier are more likely to make financial plans (Heller & Factor, 1991). However, lack of information and misinformation among families and professionals has often lead to inappropriate plans that do not protect government benefits or that deprive adults with intellectual disabilities of their rights. For example, some families will money or property to another child with the hope that the child with intellectual disabilities will be taken care of. There are many reasons why this approach is fraught with problems, including the high divorce rate and the encouragement of dependency of the adult child with a disability on another family member. Another example is the tendency of families to obtain full guardianship rather than partial guardianship where some of the rights of the adult with disability are retained. There has been very little research on advance directives: that is, plans regarding future health care needs.

7.15.4.4 Sociocultural Issues

The caregiving experience for families cannot be understood without taking into consideration their sociocultural context. We are just beginning to examine the commonalities and differences in the later-life experiences of families from different countries, ethnic backgrounds, racial heritage, and socioeconomic level.

7.15.4.4.1 Comparisons across countries

While this chapter primarily describes the service trends and research findings from the USA, many of the same trends are occurring in other countries, particularly in developed countries. For example in Germany, Adam (1992) has estimated that, from 1988 to 1998, the percentage of adults with intellectual disabilities receiving services in the Wilhlemshaven region will increase from 17% to 26% in the 50–64 year age group and from 3% to 4% in the over 60 years age group. The trend to close or phase down institutions and to develop community programs has been proceeding rapidly in Europe. For example, between 1980 and 1993 in Scandinavian countries and in the United Kingdom there has been a decrease in the institutional population at an average rate of 4.25% per year (Hatton, Emerson, & Kieman, 1995). As in the USA many countries have long waiting lists for residential services. Breitenbach (1995) has noted that in France there are few openings in residential programs for older adults who are living with families, as priority is given to persons already in the residential service system. Van Walleghem (1993) noted the long waiting lists awaiting older parents seeking residential services for their relative with intellectual disabilities in Belgium.

In a cross-national comparison Heller, Haveman, and Van Berkum (1996) report that in comparison with older caregivers in the USA, parents in the Netherlands are more likely to make future plans, have fewer unmet needs for supports, and perceive more caregiving burden. These results could be explained by differences in the two service systems. In the Netherlands the fact that families made more plans could be attributed to their greater use of case management services and less apprehension about the service system. The higher stipend given to persons with intellectual disabilities in the Netherlands than in the USA may explain the lower need for information about future financial planning. In both countries high unmet service needs and poor health of the adult with intellectual disabilities were related to higher caregiving burden.

In a study comparing older caregivers in the USA with caregivers in Ireland Seltzer et al. (1995) found that in Ireland caregivers were less likely to make future plans, had poorer health, a smaller support network, more parenting stress, and less life satisfaction. There were also differences between caregivers in the Republic of Ireland and in Northern Ireland, with caregivers from the Republic of Ireland reporting more social isolation. Both of these studies demonstrate the potential role that culture, society, and service availability and expectations play in shaping the caregiving experience for families.

7.15.4.4.2 Culturally diverse groups in the USA

Only in the 1990s have studies begun to examine caregiving issues among families of persons with intellectual disabilities from various minority groups. These studies have focused on residential placement and future planning, use of informal and formal supports, and perceived caregiving burden and satisfaction. Comparisons of African-American and white families have found that African-American families are less likely than other families to place their relative out of the family home (Markwardt, Heller, Rowitz, & Farber, 1993; Pruchno et al., in press). One reason could be attributed to difficulties minority families experience in accessing services, either due to lack of awareness or lack of available services in their communities (Vidal de Haymes, 1989). In a study of Hispanic families, Heller, Markwardt, Rowitz, and Farber (1994) found that in comparison with white non-Hispanic families these families reported significantly more problems with the service system, especially in finding information and finding support groups. Others have attributed low service participation to discrimination, lack of accessibility, and lack of bilingual services (Rosenthal & Carty, 1988).

Another explanation for the higher rate of coresidence with families for African-American adults with intellectual disabilities could be that African-American families tend to have more positive attitudes towards family responsibility and greater involvement with extended families. In one study of caregivers of adults with intellectual disabilities (Heller, Rowitz, & Farber, 1992) it was found that African-American families report a similar degree of caregiving burden to that of other families, but that they report less burden on the siblings of the adult with intellectual disabilities. On the other hand, Pruchno et al. (in press) found that African-American families of adults with intellectual disabilities or mental illness experienced less caregiving burden and greater caregiving satisfaction than did white caregivers, despite being poorer and in worse health.

Among African-American families, many express an interest in having a sibling take over responsibility when the parents can no longer provide care. In one focus group, many parents have stated that their other children have been more than willing to eventually take over the care. They noted that they did not need to ask the other siblings, as they came to them to offer their support: “My son has four sisters. All of them said that they would take over.”

It has been noted that many older family caregivers of adults with intellectual disabilities do not make plans for the future care of their relative. When asked about reasons for not making future plans, two major themes have emerged: low socioeconomic status and religiosity contributed to a present-day rather than future focus. Examples of comments by African-American caregivers include: “We are close to God. God will lead us”; “We have no money with which to plan. I live from day to day. I can’t afford big dreams; I just hope to stay healthy.”

Given the changing structure and composition of the American family, and in particular the African-American family, with more single-parent households and females in the workforce, the reliance on the extended family may not be sufficient. Families will need increased help in providing support to their relative with intellectual disabilities and more information on residential services and financial planning so that they can secure a desirable future for their relative. A critical aspect for many minority families will be outreach to families not only through the aging or disability networks, but also through churches and other community resources.

7.15.5 FAMILY SUPPORT INTERVENTIONS AND POLICIES

As adults with intellectual disabilities and their parents age, they likely face some functional declines and greater difficulty in maintaining independence. Yet this group of families tends to make low use of services. Most of these families have been quite self-reliant in providing care for their child over the years. This section describes their service needs and use, the importance of formal services in sustaining their ability to provide care, and different models of service provision.

7.15.5.1 Family Needs and Service Use

As their children make the transition from childhood to adulthood, parents of adults with intellectual disabilities face the unique challenge of dealing with their own age-related declines in health and energy and the decreased formal services available for adults with a disability. Older parents have major unmet needs for information regarding residential programs, financial plans, and guardianship (Heller & Factor, 1994; Kelly & Kropf, 1995). Also, they have major needs for case management and advocacy (Kelly & Kropf, 1995) and financial assistance (Fujiura & Roccoforte, 1990). Fujiura and Roccoforte found that families spent an average of 20% of their pretax annual income on unreimbursed expenses for their adult relative with intellectual disabilities residing with them. In addition to needing services for their child, parents may also need services for themselves through the aging network.

Families often are unsure of appropriate goals and programs for their adult children and they may have reservations about using either the aging or intellectual disabilities formal services system. Many older caregivers have not had formal services available in the past and express fear that placement is the main aim of the formal service system (Janicki, 1996). Todd and Shearn (1996) note that for some families who have made a career of parenting, use of services reduces their roles and reduces their sense of purpose and identity. Other reasons why some families are reluctant to accept agency services are: (i) previous negative experiences, (ii) difficulties talking with providers who offer advice families do not agree with or who are not sensitive to their concerns, (iii) complex eligibility criteria for some services, and (iv) inflexibility of services. On the other hand, some families may have been long-term users of services. They may have been active in developing parent organizations, support groups, or provider agencies. The service families are most likely to use for their child is day programming. While many families desire respite, frequently the public financial resources for respite care are insufficient to meet demand.

The extent to which formal services improve the well-being of the caregiver is unclear. In our studies (Heller & Factor, 1991, 1993b) perceived unmet formal service needs was a key factor influencing the well-being of parents, with high unmet needs being related to caregiving burden. Use of services also has been related to parents' perceived current and future ability to provide care (Englehardt, Brubaker, & Lutzer, 1988).

7.15.5.2 Progam Models

Several models of support interventions help families in sustaining care and in coping with their relative. These include: (i) support and psycho-educational groups, (ii) outreach through the aging network, and (iii) family support programs.

7.15.5.2.1 Support and psycho-educational groups

At least one-quarter of the older family caregivers interviewed (Heller & Factor, 1991) expressed an unmet need for a support group. Support groups are one type of intervention that can provide aging families with information, skills, and support for helping the adult with intellectual disabilities, for helping themselves cope with the emotional aspects of caregiving, and for developing future plans. Smith, Majeski, and McClenny (1996) report that older families who participated in psycho-educational groups geared to caregivers of adults with intellectual disabilities most valued the information on future planning and formal services and the opportunity to interact with other parents having similar concerns. Parents who did not coreside with their adult child having intellectual disabilities reported benefitting the most from information on quality of residential programs. Although Smith et al. (1996) report family satisfaction with psycho-educational groups, few older family caregivers attend such events. Even when they would like to participate, older family members may have difficulty with transportation or scheduling. While these short-term interventions may ease stress on a short-term basis or provide some needed information, they do not tend to have long-lasting impacts. Also, Abel and Nelson (1990) caution that educational programs for caregivers can undermine the caregiver's own problem-solving capacity and sense of control over the situation.

Support groups for caregivers of elderly relatives have had modest benefits as measured by rating of participants' well-being and caregiving burden (Zarit & Toseland, 1989). Among families of persons with mental illness, they have been shown to help caregivers gain a sense of self-control and lower burden in some cases (Anthony & Blanch, 1989). No research has examined the effectiveness of support groups that are not psycho-educational groups on older caregivers of adults with intellectual disabilities.

7.15.5.2.2 Outreach through the aging network

Since US federal legislation was passed that targeted collaborative projects between the aging and developmental disabilities networks, there have been several model projects that targeted elderly caregivers of adults with intellectual disabilities. These projects entail coordination, network building, and internetwork coalition building (Factor, 1996; Janicki, 1996) between not only the aging and disabilities service agencies, but also other community agencies. One example of such a project is the Hispanic Coalition Network (Factor, 1996) that was developed in Chicago, which organized an Hispanic Fair that brought in 120 providers, elderly Hispanic family caregivers, and other community resources in a local community. In order to attract the families, health screenings and food were offered. Many families who had not previously received needed services became aware and linked up with a variety of services. Another example of a caregiver project is the New York Caregiver Assistance Project (Janicki, 1996), mentioned earlier in this chapter. That project operated from a mode which assigned outreach and assistance functions to a host agency. Major components included a needs assessment, targeting of special households, and a program of promoting community awareness. The project found that area agencies on aging could provide a safety valve for potential crises that would have resulted in immediate placement demands and referral to potentially more costly developmental disability programs. Another major finding was that working with cultural organizations within the local community resulted in greater willingness of families to accept services.

7.15.5.2.3 Family support public programs

In the 1980s and 1990s there has been a growing expansion of family support programs for families of persons with intellectual disabilities in the USA. Most of the earlier programs provided discrete types of services which were directed by agencies and by professionals. These included primarily respite, counseling, and parent training services. Later, cash subsidies were added in some states. However, with the emerging movement towards community empowerment and recognition of the need for persons with disabilities to remain in their communities and "natural" settings, new family-driven models have been promulgated. Generally, family support programs have been based on the goals of strengthening family functioning and enhancing growth and development of individuals and the family. Ultimately, most of these programs have the goals of maintaining persons with intellectual disabilities within the family home. As of 1995, 21 states had family support legislation (Bergman & Singer, 1996). Between 1988 and 1992 there has been an increase in intellectual disabilities state expenditures for family support services from 171 million to 277 million dollars allocated and from 163 330 to 198 827 families served (Braddock et al., 1995). While there has been an expansion of family support services, funding for them only represents 2% of expenditure for intellectual disabilities services (Braddock et al.) and many of these programs only target children.

Most of the innovative family support programs have developed models of consumer control in which families determine how resources are spent. These are based on the premise that families usually know best what it takes to maintain their relative with a disability in the family home. They also acknowledge the importance of using the informal network, including relatives, neighbors, and friends by allowing families to pay them for support services.

Most of the studies evaluating the impact of these family support programs have focused on families of children. These studies have documented their success in reducing stress and increasing life satisfaction for caregivers (Herman, 1991; Meyers & Marcenko, 1989). In a study of a family support program in Illinois geared to adults, it was found that family subsidies of about $1 300 combined with service facilitation and consumer control of services and expenditures resulted in many positive benefits over a 4 year period (Heller, Ruch-Ross, & Kopnick, 1995). In comparison with families who did not receive these services through a lottery selection process, the participant families reported greater caregiving satisfaction and greater feelings of competence and self-efficacy in helping their relative with intellectual disabilities. In addition, benefits included more community integration and improved interpersonal relations of the adult with intellectual disabilities, fewer unmet services needs, more satisfaction with services received, and less need for out-of-home placement. Also, families who participated were more likely to engage in legal and financial planning for their relative.

With the trend to community inclusion and consumer control of resources, and with pressures to cut costs by reducing residential services, there is likely to be an increase in family support programs. For older family caregivers this can result in added resources for maintaining caregiving within the family. However, with the advent of managed care approaches there is the danger that the funds will be too small or that sufficient residential options will not be in place for those families not able to provide care in the home setting. The Illinois family support program provides twice more funds per family than most of the other states' programs and is one of the few that targets adults.

7.15.6 RESEARCH DIRECTIONS

7.15.6.1 Summary of Research

The research on family caregiving for adults with intellectual disabilities is indicating tremendous variability in families' responses and the importance of understanding the life course and social context within which families operate. Some families devoted much of their lives to parenting a child with a disability through years when there were few services. Other families placed their relative out of the home and had various levels of continued involvement with their relative. With the advent of parent advocacy programs some families became active in promulgating new and expanded services in their communities. Certainly, during these eras there have been major demographic trends that have affected families' ability to provide care.

While expectations of family caregiving are higher, the resources within the family have often been diminished. This has been most acutely felt by women who most often are the primary caregivers. Yet, other members, such as fathers and siblings, also play crucial roles in supporting the adult with intellectual disabilities, not only during the parents' lifetime, but also afterwards.

Support programs and interventions have been one resource helping family caregivers. These have included support groups, counseling, parent training, respite, and cash subsidies. The effectiveness of these programs in helping families care for their relative and in enhancing the lives of the family members is being studied. Little is known about the best methods for providing supports to families. However, it is clear that, as they age, many families who have relied on their own resources will require some help from the formal service systems.

7.15.6.2 Research Agenda

To improve theoretical understanding of the caregiving experience and of ways to promote positive coping among families of adults with intellectual disabilities, comparative research across disability groups, across developmental periods, and across culturally diverse groups is needed. Most of the research up to 1997 focuses on one type of disability at one developmental period, usually that of parenting young children or of caregiving in later life. There are only a handful of studies that span different age phases, and these studies are hampered by their cross-sectional methodology.

With the exception of the research conducted by Seltzer and Krauss and their colleagues and by Heller and Factor there have been no longitudinal studies examining family caregiving among older family caregivers of adults with intellectual disabilities. With more longitudinal data it will be easier to delineate causal directions.

Another aspect that needs to be pursued further is the reciprocal nature of family caregiving and the impact of reciprocal supports on various family members. This line of research needs to take into account the perspectives of various family members—including the adult with intellectual disabilities, who may view the situation differently. Fathers and siblings also have been largely neglected in research; yet they play a critical role in supporting the adult with a disability and the mother.

There is little data on the impact of cultural, national and local differences on families' caregiving experience. There is a need for more studies that include various cultural groups and that examine the impact of differences in cultures and service networks in different communities, states, and countries. The challenge in this type of research is to disentangle the effects of socioeconomic status, culture, and service network differences on families.

Finally, more needs to be known about ways to help families cope. One way is to learn from families who have coped successfully, have nurtured a positive family climate, and have enhanced the development of the member with intellectual disabilities. These families have been able to successfully negotiate both the fulfillment of their own roles and the development of the adult with disabilities. In addition to quantitative data, there is a need for qualitative, ethnographic data to more richly elucidate this coping process .

Another way to learn more about ways to help families is to study the effectiveness of interventions and public programs. Most of the research is anecdotal or lacks empirically-sound comparison groups. In studying these interventions, a longer-term perspective needs to be taken. For example, to understand the impact on actual placement, a span of more than just 1 year must be looked at. As service models evolve examinations of both the mode in which services are delivered and the outcomes of these approaches are needed. Satisfaction of adults with disabilities and their families with the process and outcomes should be a major determinant of the program's success.

ACKNOWLEDGMENT

7.16.1 INTRODUCTION

Falls are a common experience among older adults. Approximately one-third of community-dwelling older adults (Studenski et al., 1994; Tinetti, Speechley, & Ginter, 1988; Walker & Howland, 1991), 20% of older adults in acute care facilities (Kay & Tideiksaar, 1990), and half of older adults in long-term care facilities (Speechley and Tinetti, 1991; Tinetti, Baker, et al., 1994; Wright, Aizenstein, Volger, Rowe, & Miller, 1990) fall each year. Within a year, half of these fallers will have fallen again (Hernandez & Miller, 1986; Wolinsky, Johnson, & Fitzgerald, 1992). Studies suggest that these estimates may underestimate true fall rates. For example, Cummings, Nevitt, and Kidd (1988) found poor recall of past falls among community-dwelling older adults. Rates among institutionalized elderly may be higher as well, due to under reporting of noninjurious falls. This is a particular concern in studies utilizing chart reviews as their primary means of data collection (Kanten et al., 1993).

While the probability of falling is greater among nursing home residents, the vast majority of falls (85%) occur among community-dwelling older adults (Tideiksaar, 1993b). This is due to the greater number of older adults residing in the community; only 5–10% of older adults reside in long-term care facilities (Brock, Guralnik, & Brody, 1990). Nearly 50% of falls result in minor or soft tissue damage (Nevitt, Cummings, Kidd, & Black, 1989), while 10–20% result in more serious injury (Tinetti et al., 1988). Hospital admission follows 5–10% of falls (Gibson, Andres, Isaacs, Radebaugh, & Wore-Peterson, 1987) and falls account for 10 – 15% of emergency medical service (EMS) transports and trauma admissions among older adults (Mosenthal, Livingston, Elcavage, Herritt, & Stucker, 1995; Wofford, Heuser, Moran, Schwartz, & Mittelmark, 1994). Hip fractures result in tremendous physical and emotional consequences and an increased risk of death. Over 90% of the approximately 215 000 people who experience hip fractures each year in the USA (National Institutes of Health, 1991) occur as a result of a fall (cited in Graafmans et al., 1996). They are a leading cause of decreased independence and entrance into long-term care facilities (National Center for Health Statistics, cited in Greenhouse, 1994). Nearly half of older adult patients who enter a hospital due to a fall become long-term care patients following their injuries (Kay & Tideiksaar, 1990). Increased morbidity is also associated with falls (Rubenstein, Josephson, & Robbins, 1994). In 1987, 75% of all deaths due to falls in the USA occurred among older adults, even though they made up only 12% of the population at that time (Greenhouse, 1994).

The goal of this chapter is to provide an overview of the empirical literature on falls among older adults, beginning with a consideration of a few conceptual and methodological issues that plague this research area, and proceeding through the consequences of falls, factors associated with falls, and finally fall prevention. This is not intended to be an exhaustive review of the falls literature. Interested readers are referred to Tideiksaar (1997) for additional consideration of this literature.

7.16.2 CONCEPTUAL AND METHODOLOGICAL ISSUES

What constitutes a fall? The answer to this question varies according to who is being asked. One of the major problems with falls research is the failure to adopt a single definition of falls. Most definitions are consistent with the notion that a fall is an unintentional event that leads to an individual coming to rest on the ground or a lower level. However, specific aspects of a fall may be excluded from one study's definition while included in another. For example, Tinetti et al. (1988) defined a fall as "an event which results in a person coming to rest on the ground or other lower level, not as the result of a major intrinsic event (such as a stroke or syncope) or overwhelming hazard" (p. 1702). However, Hernandez and Miller (1986) included in their definition any abrupt accidental or purposeful change in position which could potentially result in an injury. While both definitions are acceptable, they make comparable results between the two studies difficult to interpret. In an effort to establish guidelines into research on falls, the Kellogg International Work Group (1987) proposed the following definition of a fall: "A fall is an event which results in a person coming to rest inadvertently on the ground or other lower level and other than as a consequence of the following: sustaining a violent blow, loss of consciousness, sudden onset of paralysis, as in a stroke, or an epileptic seizure" (Gibson et al., 1987, p. 4). Since this definition was proposed, it has been utilized in several studies. The use of such a single definition allows for comparisons across various studies, which has been difficult with the majority of published fall studies.

The definition of a fall is not the only problem found in the falls research literature. Diverse subject pools, different criteria for fallers, and disparate outcome measures also preclude comparisons among studies. Subjects in different studies vary along a variety of demographic variables (e.g., housing status, age, and health). Very few studies have included a wide age range of subjects (i.e., middle age and oldest-old adult subjects) and none have included samples across both community-dwelling older adults and nursing home residents. While studies have reported the populations investigated, sample differences may account for differences in the results rather than the experience of a fall. Studies have defined fallers both as individuals who have fallen at least once and individuals who have fallen two times or more. Since most results are based on differences between fallers and non fallers, discrepancies in criteria for group inclusion may account for variance in results. Finally, the use of a variety of outcome measures complicates the interpretation of results from various studies. Fall rates, total number of falls, and percentage of group experiencing a fall have all been used as outcome measures in studies of fall risk factors. These three outcome measures address different aspects of falls and are not always directly comparable. For example, a study showing a high total number of falls may have a low percentage of fallers and several repeat fallers may account for the large total number of falls. In contrast, a high total number of falls may be due to a relatively small number of falls among a large number of fallers. When interpreting or comparing the results of various studies, it is imperative that these fundamental methodological differences be considered.

7.16.3 CONSEQUENCES OF FALLS

7.16.3.1 Physical Consequences

Falls can result in a variety of physical consequences, ranging from minor injuries (e.g., abrasions, contusions, sprains, lacerations) to serious injuries (e.g., head trauma, spinal cord injuries, fractures, internal injuries). Thirty-one percent of falls result in minor injury and another 6% result in serious injury (Morse, Tylko, & Dixon, 1987). Though the percentage of falls resulting in fractures ranges from only 1–6% for the USA (Tinetti et al., 1988), France (Vellas, 1985, cited in Gibson et al., 1987) and Canada (Gryfe, Amies, & Ashley, 1977), "most deaths and long-term disability [related to falls] are … due to the complications of fall-related fractures, especially hip fractures and other fractures among the elderly" (Melton & Riggs, 1985, p. 525). In view of the significance of fractures, falls related to fractures will be the focus of this section.

The most common fractures resulting from falls are to the wrist, upper arm, and pelvis (Melton & Riggs, 1985). The occurrence rate of fractures to the hip, wrist, pelvis and upper arm increases with age (Melton & Riggs, 1985), with such fractures among US, UK, and Scandinavian women outnumbering men between two and three to one (Evans, Prudham, & Wandless, 1979; Kreutzfeld, Haim, & Bach, 1984, cited in Gibson et al., 1987). The incidence of hip fractures increases after age 50 (Cummings, Kelsey, Nevitt, & Dowd, 1985), with a steep increase after age 70 (Gibson et al., 1987). Falls in the USA result in an estimated 215 000 hip fractures each year, resulting in 100 000 new cases of severe long-term disability (National Institutes of Health, 1991). On average, hip fractures result in a 21-day acute-care hospitalization (Baker & Harvey, 1985). The National Institutes of Health (1991) estimate that, by the year 2030, there will be 400 000 hip fractures incurred each year.

Of those individuals who are independently ambulatory prior to incurring a hip fracture, up to 75% will require ambulatory assistance for 6–12 months following the fracture (Tideiksaar, 1997). Of those hospitalized for a fall, only 50% survive one year (Tideiksaar & Kay, 1986). For those over the age of 85 residing in a nursing home, one fall out of five ends in death (Baker et al., 1984 as cited in Tideiksaar, 1989). Each year in the USA, 1800 falls are recorded as immediately fatal (Baker, O'Neill, & Karpf, 1984 as cited in Baker & Harvey, 1985).

Head trauma is a relatively common consequence of falls. Most head injuries resulting in acute hospitalization are from falls (Saywell, Woods, Rappaport, & Allen, 1989). Curtis, Wofford, and Branch (1995), cited in Tideiksaar, (1997), found that 54% of older adults hospitalized for subdural hematomas had fallen shortly before they were hospitalized.

Falls sometimes result in the faller remaining immobile for a period of time. Immobility secondary to a fall can result in hypothermia, broncho pneumonia, pulmonary emboli, and dehydration, all of which may lead to death (Mitchell, 1984; Tideiksaar, 1993c; Tideiksaar & Kay, 1986). The amount of time a person remains immobile immediately following a fall is termed "lie time" and is a marker for weakness, illness, and social isolation (Gibson et al., 1987). Moreover, lie time is a mortality risk factor. British studies indicate that lie times of at least 60 min are associated with death within six months (Wild, Nayak, & Isaacs, 1981, cited in Gibson et al., 1987). Unfortunately, data from France suggest that long lies are not uncommon. In Toulouse, 10 of 48 elderly patients hospitalized for falls had laid on the ground for an hour or more, and one for three days (Vellas, 1985, cited in Gibson et al., 1987).

7.16.3.2 Psychological Consequences

Older adults experiencing a fall also face potential emotional consequences. However, the psychological consequences following a fall are often ignored in falls research. Psychological consequences may lead to further physical decline. For example, an individual who experiences a fall may lose confidence in his/her ability to perform activities without falling again. Therefore, in an effort to avoid further falls, he/she restricts his/her activities. The decline in activities leads to a decline in physical health and muscle tone. If an individual remains inactive, he/she can become weak to the point of becoming unable to perform activities. Thus, psychological factors may result in decreased physical abilities and increased physical dependence.

Psychological factors have been examined as both risk factors and consequences of falls. Due to the retrospective nature of most falls research, it is difficult to determine if psychological problems related to a fall were present prior to, or appeared as a consequence of, a fall. This issue is further complicated by the fact that psychological factors can be both consequences and risk factors of falls. Many older adults experience a loss of confidence, depression, or fear of falling after a fall (Downton & Andrews, 1990; Tinetti, Richman, & Powell, 1990; Tinetti et al., 1988). The presence of any of these psychological problems may lead to decreased mobility and further physical decline as described previously.

The failure of many falls researchers to collect information on psychological consequences of falls reveals an emphasis on medical factors rather than psychological factors within falls researchers. Psychological factors are related to the occurrence and outcome of falls. Simpson and Mandelstam (1995) found that about 23% of hospital patients who had experienced a fall refused to participate in physical therapy training even though it was determined that they were capable of participation. Given that the patients were physically capable of participation, psychological factors likely account for the patient's refusals. This finding and others discussed below suggest that confidence in abiding abilities, self-perceived health status, depression, and fear of falling can have detrimental effects on health, activity level, and life satisfaction. It is important that research into psychological factors be conducted and prevention and treatment programs be developed.

Tinetti, Richman, and Powell (1990) developed the Falls Efficacy Scale (FES) to measure an individual's confidence in his/her ability to avoid a fall while performing specific activities. This scale was developed initially as a measure of fear of falling. Fear was defined as "low perceived self-efficacy or confidence at avoiding falls" (p. P239). Therefore, it is utilized more accurately as a measure of confidence. Decreased confidence has been shown to be related to a history of falls (Tinetti, Mendes deLeon, Doucette, & Baker, 1994). Poor ability to estimate mobility was a significant predictor of falls in a study conducted by Morse, Morse, and Tylko (1989). Poorer ability to accurately predict overall physical abilities appears to place one at risk of experiencing a fall.

Falls influence health ratings in otherwise healthy individuals (Cwikel, Kaplan, & Barell, 1990). People who have experienced a fall rate their health as being poorer after a fall than nonfallers (Cwikel et al.). Subjective health ratings are also related to severity of injury due to a fall. People requiring emergency room visits after a fall rate their health as poorer than fallers with less severe physical consequences (Cwikel et al.). Further, longitudinal studies demonstrate that subjective health rating is a predictor of morbidity and mortality (Kaplan, Barell, & Lutzky, 1988 cited in Cwikel et al.). Intuitively, it makes sense that people who report poor health and ability would fall more frequently, especially if their self-report is accurate. However, individuals who are actually in poor health but report good health (i.e., high confidence in a poor ability) may be more at risk. It is difficult to determine if subjective health ratings reflect actual health status. A complex interplay among reported health, actual health, and falls may be involved and warrants further investigation.

Depression has been found to be associated with falls (Tinetti et al., 1988), recurrent falls (Luukinen, Koski, Laippala, & Kivela, 1995), and to distinguish between groups of fallers and nonfallers (Tinetti, Liu, & Claus, 1993). The presence of depression significantly and independently predicted falls in community-dwelling psychogeriatric patients (Asada, Kariva, Kitarjima, Kakuma, & Yoshioka, 1994) and hospital patients (Soja, Kippenbrock, Hendrick, & Nyhius, 1992). Furthermore, antidepressant medications have been found to be associated with decreased risk of falling (Asada et al.), possibly due to the alleviation of depressive symptoms. These findings suggest that depression is a risk factor for falls. However, the majority of studies are retrospective in nature and should be interpreted with caution. Depression is a common diagnosis applied to older adults; therefore, it is difficult to determine from cross-sectional data whether depression is related to the occurrence of a fall or was a premorbid condition. Depression is often measured within fallers and nonfallers and then the two groups are compared. Researchers then conclude from these comparisons that the presence of depression is predictive of falls. However, a study which finds depression as a risk factor for falls by utilizing data collected after a fall may not be accurate. Findings may indicate that falls are predictive of depression. Prospective studies of depression and falls are needed to clarify the impact falls have on the expression of depression.

Fear of falling is reported by both older adults who have and have not fallen. Between 20 and 33% of nonfallers (Downton & Andrews, 1990; Howland, Peterson, Levin, & Fried, 1993) and 48 to 56% of fallers (Downton & Andrews, 1990; Tinetti et al., 1988) reported being afraid of falling. Walker and Howland (1991) found fear of falling to be the most prevalent fear reported by older adults living in a housing community for the elderly. Studies investigating the fear of falling are hindered greatly by the lack of a single definition or measure of fear of falling. Every study utilizes a different measure and differences in definition influence the results. For example, the FES discussed earlier is often used as a measure of fear of falling when it actually measures confidence in the ability to avoid a fall. Results from studies utilizing this scale cannot be compared with studies utilizing a direct measure of fear of falling. Using an open-ended question on fears, Null-Kogan (1996) found fear of falling to be the second most frequently reported fear among community-dwelling older adults. Of the 50 participants in this study, 68% reported at least a little fear of falling. Howland et al. (1993) demonstrated that injurious falls may create higher rates of fear of falling. Forty-one percent of people who experienced injurious falls reported a fear of falling as opposed to 29% of those who experienced noninjurious falls. Fear of falling is associated with higher dependency, greater physical symptomatology (Downton & Andrews, 1990), greater drug consumption (Downton & Andrews, 1990), higher reported depression and anxiety (Arfken, Lach, Birge, & Miller, 1994; Downton & Andrews, 1990; Howland et al.), restriction of movement and activities (Howland et al.), and increased morbidity. People with a severe fear of falling after a fall are more likely to have long hospital stays and die (Murphy & Isaacs, 1982).

One of the most serious consequences of falling is the subsequent restriction in movement accompanying the fear of future falls. In a study of nursing home residents using wheelchairs, 76% reported they used wheelchairs voluntarily because they were afraid of falling if they tried to walk (Pawlson, Goodwin, & Keith, 1986). Between one quarter and one half of fallers stated that they restricted or avoided activities due to fear of falling (Howland et al., 1993; Nevitt et al., 1989; Tideiksaar, 1993c; Tinetti, Mendes de Leon, et al., 1994). Restriction in movement can lead to social isolation and withdrawal as well as an increased risk of falling due to decreased muscle strength and mobility. Prolonged bed rest can lead to bone demineralization, lung and peripheral circulation stasis, skin and soft tissue damage, and altered supply of oxygen to the brain resulting in confusion and cognitive problems (Commodore, 1995). It can also lead to joint contractions, balance loss, pneumonia, pulmonary emboli, and death. Fear of falling and restriction of movement appear to be more common in people with a history of past falls.

7.16.3.3 Economic Consequences

It is estimated that the direct and indirect costs of accidental injury in the USA is between 75 and 100 billion dollars annually (Committee on Trauma Research, Commission on Life Sciences, National Research Council, & Institution on Medicine as cited in Urton, 1991). Falls are the leading cause of accidental injury. The direct costs include medical treatment, rehabilitation, nursing home care, medical equipment, and loss of productivity by the faller and their caregivers. A study conducted in Seattle in 1983 found that 1740 fall-related injuries cost US $500 000 for emergency room services alone (Hongladarom, 1983 cited in Commodore, 1995). The estimated cost of acute care for fractures is roughly 10 billion dollars each year (Sattin, 1992 cited in Tinetti, Baker et al., 1994). Hip fractures are the most serious fractures in terms of cost. In 1987–1988, a study conducted in the UK reported expenses of 160 million pounds for the medical treatment of hip fractures (Gibson et al., 1987). The annual cost of hospitalization and long-term care related to fall injuries is 2.5 billion dollars in the USA (Tideiksaar, 1997). Each year billions of dollars are spent to care for people after they experience a fall.

The economic cost of falls can also be indirect. For example, the additional costs of staff time and allotted hospital days for inpatient falls can mount quickly following a fall. Moreover, the additional care required of a fall victim is time taken away from other residents in the facility. Since falls are the leading cause of accidental traumatic injury in individuals over the age of 65, emergency medical costs are also affected by falls and fall-related injuries (Tinetti & Speechley, 1989). Campbell, Reinken, Allan, and Martinez (1981) found that patients admitted to a hospital for traumatic injury experienced longer stays than patients admitted for a nontrauma-related reason (43 days vs. 25 days). Individuals experiencing numerous falls are more likely to have longer stays and be placed in nursing homes (Wolinsky et al., 1992). In the UK and France, one of the leading causes of admission to geriatric hospitals, residential homes, and nursing homes is falls not resulting in fractures (Gibson et al., 1987). The demands of frequent fall-related trauma influence the allocation of resources.

Falls also impact psychological, familial, and societal resources. Loss of independence, depression, and fear of falling require emotional and psychological resources of health care providers, fallers, and families. For example, pain resulting from a fall can have far-reaching effects on an individual's functioning. Families may experience disruption in routines as family members adjust to living and interacting with a physically diminished individual. Once-independent members may require assistance from family members who must rearrange schedules or living situations to accommodate the new demands of caregiving. Finally, community resources may be allotted differently to meet the needs of physically limited older adults. For example, more funds may be designated for use in senior centers or elder care programs rather than building a new school. Falls can have far reaching effects on many diverse areas.

7.16.4 RISK FACTORS AND THE CONTEXT OF FALLS

A substantial number of extrinsic and intrinsic factors associated with falls have been identified. It is important to note that when considering these individual factors, the reader should be aware of the general finding that multiple risk factors are involved with any particular fall.

7.16.4.1 Extrinsic Factors

Every fall occurs within an environment. However, external or extrinsic factors are rarely the sole cause of individual falls. In a study conducted by Rubenstein et al. (1988), no fall could be completely explained by environmental factors. Most falls occur as a result of both intrinsic and extrinsic factors. For example, an older adult experiencing depression may trip over the edge of a rug overlooked due to inattentiveness. This might not have occurred had the individual been mentally healthy and attentive. Environmental factors are associated with approximately one-third of falls occurring within the home and two-thirds of falls occurring outside of the home (Nevitt et al., 1989). This may be an underestimation of the role of environmental factors due to the retrospective nature of research into falls. A faller's memory of factors involved in a fall may be faulty due to injuries, personal beliefs about the cause of the fall, or the passage of time. Moreover, a fall can alter the appearance of the physical environment (e.g., an obstacle may be moved following a fall), thereby influencing the recall of relevant environmental information. In a study investigating the prevention of falls, 53.8% of residents in a skilled nursing care facility and 35.1% of residents in a board and care facility were given recommendations regarding changes to their environment (Rubenstein et al.). The high rate of environmental hazards led the investigators to project that environmental factors may be involved in as many as 50% of falls. Some of the extrinsic factors considered in previous research are considered below.

7.16.4.1.1 Time of fall

Research into time-related factors has produced conflicting results. Several studies have found peak times for the occurrence or nonoccurrence of falls (Brown & Edelstein, 1995; Graffmans et al., 1996). Several studies suggest higher occurrences of falls in institutions during the morning and evening shifts (Marx, Cohen-Mansfield, & Werner, 1990; Walker & Howland, 1991), but no consensus exists across studies. Quail (1994) and Walker and Howland (1991) reported that increased fall rates occurred at times of increased activity. In their studies, falls were more likely to occur during toileting at night and while performing activities during the day. In addition, Heslin et al. (1992) found that falls from beds were more likely to occur at night. Thus, the location of specific activities influenced where falls occurred. It appears that falls are more likely to occur at periods of increased activity, and time of day influences which activities are being performed. The activities most frequently reported at the time of a fall were ambulation and transfer of position (Heslin et al.). These studies suggest that the differential effects of time of day reported in individual studies may be indicative of increased periods of activity.

Seasonal influences also impact fall rates. Commodore (1995) reported an increased number of falls during the winter months. This was likely due to increased numbers of slippery surfaces (e.g., ice) and outdoor environmental hazards (e.g., snow covering holes). Mobility is also restricted by bulky clothing during the colder winter months. Although it has not been examined in the literature, increased physical activity during the summer months may lead to a similar increase in falls during the summer months. More information is needed on seasonal fall rates to investigate seasonal contributions.

7.16.4.1.2 Location of fall

Previously mentioned fall rates differ across residential status. For example, nursing home residents are more likely to experience falls than community-dwelling older adults. In addition, recently admitted patients to a nursing home are more likely to fall than long-term residents (Quail, 1994), with over 60% of nursing home residents experiencing a fall during their first year (Tinetti, 1987). The unfamiliar environment of the nursing home is likely to contribute to many falls occurring with newly admitted residents.

Rubenstein et al. (1988) reported that 80% of falls occurring in a multilevel care facility occurred indoors. Similar results were found in a prospective study in residents of homes and apartments for the elderly in Amsterdam (Graffmans et al., 1996). Among acute care patients, 65% of falls occur in the bedroom, half of these occurring from the bed (Heslin et al., 1992). It is unclear if fall rates coincide with length of time spent in a specific location. For example, Brown and Edelstein (1995) found falls among psychogeriatric inpatients to occur more frequently in the bedroom, hallway, dining room, dayhall, bathroom, and outside. However, no overall percentage of time spent in these locations was reported. If an individual spends 75% of the day in bed, the chances of a fall occurring in his/her bedroom is higher than one occurring in another location. Lipsitz, Jonsson, Kelley, and Koestner (1991) found that older adults frequently fell when they ambulated or transferred position (e.g., stood up from a chair). It is likely that the frequency of activities occurring in specific locations influence fall rates in those locations.

Stairs are hazardous for many older adults. In one study, 10% of falls among community-dwelling adults occurred around stairs (Tinetti et al., 1988). Decreased visual perception may lead to miscalculation of the length or height of individual steps. Archea (1985), cited in Gibson et al. (1987), found that most accidents involving stairs occurred while the individual was descending the stairs and were often related to poor architectural design. Stair-related accidents occur more frequently among young-old adults (65–75 years) (Abrams, 1984 cited in Gibson et al.). This may be due to decreased use of stairs by old-old adults or increased caution while using them. However, old (75–85 years) and oldest-old (85 + years) adults experience more serious consequences from falls on stairs than young-old adults (Gibson et al.). Where a fall occurs can be influenced by the amount of time spent in a location, activities that occur in a location, and particular environmental characteristics of the location.

7.16.4.1.3 Walking aids

Improper use of a walking aid (e.g., cane, walker) is a common contributory factor to a fall. Fallers are more likely to use an ambulatory aid (Mahoney, Sager, Dunham, & Johnson, 1994; Morse et al., 1989; Robbins et al., 1989a, 1989b). It is unclear whether this is a direct result of previous falls or unrelated conditions. Tinetti (1987) found the use of a walking aid to be the most common external factor associated with falls in a nursing home population. Improper use of walking aids is also associated with the inability to get up following a fall (Tinetti et al., 1993). As previously discussed, individuals who are unable to get up after a fall are more likely to experience serious physical consequences than individuals who are able to get up after a fall. The increased risk of falling due to use of walking aids may be due to reasons related to the use of the walking aid. Campbell, Borrie, and Spears (1989) stated that the increased risk due to the use of walking aids was a reflection of frailty or poor mobility requiring the use of such aids. If this is found to be true, it is unknown if improper use of these aids would be an additional risk factor for experiencing a fall.

7.16.4.1.4 Restraints

Restraints have been used to prevent frail or confused older adults from falling and incurring injury. In a study conducted by Heslin et al. (1992), 98% of acute care patients who fell from a bed had restrictive devices and 2% had restraints on them at the time of the fall. This suggests that many falls may occur as a result of failed attempts to remove or escape from restraints. Increasing evidence suggests that restraints do not prevent falls (Evans & Strumpf, 1990) and may be associated with injurious falls (Heslin et al.). A study investigating the impact of removing restraints found that removing them led to a significant increase in the overall fall rate but not in the rate of serious falls when compared with a nonrestrained control group (Ejaz, Jones, & Rose, 1994). Given these results, restraints should be used with caution in individuals at risk of falling.

7.16.4.1.5 Footwear

In humans, contact between the foot and the ground is necessary to provide balance and stability. Loose or poor fitting shoes contribute to instability among older adults (Quail, 1994) by reducing the stability normally provided by contact between the foot and ground. Several studies implicate loose or poor fitting footwear (e.g., slippers) as major contributors to falls (Kinsman, 1983, cited in Gibson et al., 1987). Shoes with limited traction or slippery soles may also increase the risk of falling. Research into footwear appropriate for older adults needs to be conducted.

7.16.4.1.6 Environmental hazards

Numerous articles have attempted to list hazards commonly encountered in the home. Table 1 lists many of these potential hazards. Tinetti et al. (1988) found that 25% of falls occurred as a result of tripping over an object. Environmental hazards may be more of a factor in falls by active older adults. However, with increasing age and infirmity, environmental factors may play a significant role. Few studies have investigated the impact of specific environmental hazards or the utility of making environmental changes in an attempt to decrease falls.

7.16.4.2 Intrinsic Risk Factors

An extensive array of intrinsic variables associated with falls among older adults has been examined in the literature. The factors discussed include: demographic characteristics (e.g., gender, age); physical impairment (e.g., muscle weakness, hearing loss, visual acuity loss); the results of various physical impairments (e.g., ambulation, gait, and balance problems); number, types, and amount of medications (e.g., antidepressants, sedatives), medical disorders (e.g., Parkinson's disease, cardiovascular disease); and psychological factors (e.g., denial of limitations, cognitive status). A comprehensive survey of the research addressing intrinsic factors is beyond the scope of this chapter. Therefore, representative research findings regarding the most commonly examined intrinsic variables will be discussed.

7.16.4.3 Demographic Factors

Demographic information assembled from numerous studies allows clinicians to identify populations at risk for falls. Identification of high-risk groups helps clinicians predict the risk levels of specific individual clients and can aid in the development of treatment and prevention programs.

7.16.4.3.1 Gender

The findings of research on gender as a risk factor for falling have been contradictory (Brown & Edelstein, 1995), with some studies revealing gender differences and others finding no significant differences. However, the majority of studies suggest that women fall more frequently than men (Cwikel et al., 1990; Nevitt, Cummings, & Hudes, 1991; Poster, Pelletier, & Kay, 1991) and have more risk factors associated with falls than men (Campbell et al., 1989). For example, two studies conducted in US nursing homes (Gross, Shimamoto, Rose,

Table 1 Environmental hazards.

Location	*Hazard*
Outdoors	Ice, water, holes, cracks, steps
Bedroom	Improper bed height, wheels on furniture, nonlocking bed wheels, poor lighting
Bathroom	Mats, slippery floors, low or high toilet, poor lighting, glare from floor, lack of grab bars, sliding carpets, inaccessible tub or shower stall
Kitchen	Unsturdy step stools, poor lighting, slippery linolium floors, slippery bathtubs, glare from floor, high cabinets
Living room	Low furniture, extension cords, wheels on furniture, loose rugs, poor lighting, inappropriate chair height, high steps, worn stair treads, lack of arm rests
Everywhere	Objects in pathway, sliding throw rugs, worn carpets, poor access to switches and lamps, raised door sills, lack of night lights, clutter, limited walking space, waxed or slippery floors

& Frank, 1990; Kalchthaler, Bascon, & Quintos, 1978) found a greater rate of falls among women than men. Similarly, Campbell et al. found that among community dwellers 70 years of age and older, women were at greater risk than men of falling. Moreover, a French longitudinal study of community dwellers (mean age 73) conducted by Ousset et al. (1996) found that 48% of the women and 29.8% of the men reported one or more falls during a two-year period. A Japanese longitudinal study of community dwellers conducted by Yasumura et al. (1996) found the same pattern of results as Ousset et al. However, they found a lower incidence of falls with 14.7% of men and 23.5% of women reporting at least one fall during a one-year period. The shorter time period used in the Yasumura et al. study may account for the smaller fall rate than that reported by Ousset et al.

Women incur injury as a result of falls more frequently than men (Hornbrook et al., 1994), with elderly women over the age of 75 years most likely to experience a serious injury as a result of a fall (Gibson et al., 1987). Further, Abrams (1984), cited in Gibson et al., noted that while women in the UK represent only 25% of the 65+ population, they account for over 50% of hospital-treated falls within this population. The incidence of hip fractures among women increases around age 40 and doubles every five to six years after that (Brody, Farmer, & White, 1984, cited in Gibson et al.). Differences in risks factors have also been related to gender. For example, in their prospective study, Campbell et al. (1989) found total number of drugs taken, use of drugs that can cause postural hypotension, use of psychotropic drugs, use of hypnotic drugs, mental status, and joint replacement were risk factors for women but not for men.

In contrast to the previous studies, Van Dijk, Meulenberg, van de Sande, & Habbema (1993) found a significantly higher rate of falling among male than female demented nursing home residents. Other studies have found no relation between gender and falling among patients in a general hospital (Poster et al., 1991), patients in a veteran's center and geriatric unit (Morse et al., 1987), and individuals discharged from an acute-care hospital (Mahoney et al., 1994). The different findings among these studies may be attributable to subject differences (Brown & Edelstein, 1995), with community dwelling women showing a relatively consistent higher rate of falling than community dwelling men. In the nursing home studies, higher fall rates were found among male residents with dementia (Van Dijk et al.). The two studies that found higher fall rates among women in nursing homes (Gross et al., 1990; Kalchthaler et al., 1978) appeared to include a more cognitively heterogeneous population. The confusion and disorientation that often accompanies dementia could place dementia sufferers at greater risk of falling.

Studies suggest that gender differences dissipate with age and fall rates become roughly equal after the age of 70 (Luukinen et al., 1995; Poster et al., 1991). Moreover, gender does not appear to differentially influence fall rates in elderly nursing home patients (Luukinen et al.).

7.16.4.3.2 Age

The relation between age and falls is also unclear, with numerous studies supporting and failing to support a relation. Campbell et al. (1989) found fallers to be older than nonfalling inpatients, and Kalchthaler et al. (1978) found higher frequencies of falling among older nursing home residents 40 years of age and older. Members of the Kellogg International Work Group on the Prevention of Falls by the Elderly report that most falls occur among older women (Gibson et al., 1987) even when the fall figures were adjusted for the proportion of women in the population (Prudham & Evans, 1981). Graafmans et al. (1996) found age to be related significantly to recurrent falls (two or more falls) but not to single falls among a group of community-dwelling adults in Amsterdam. The participants were 1.7 times more likely to fall for each 10-year increase in age. Wofford et al. (1994) found that adults over the age of 85 were seven times more likely to experience a fall than those aged 65–74. A study conducted by Studenski et al. (1994) found that while the probability of falling increased with age, the probability of incurring an injury as a result of a fall did not increase. This may be due to the decreased number of vigorous activities performed by older adults. For example, Speechley and Tinetti (1991) found that "vigorous" older adults were more likely to incur an injury as a result of a fall than "frail" older adults. Despite conflicting reports on risk, older adults appear more likely to experience a fall (Cwikel et al., 1990; Greenhouse, 1994; Poster et al., 1991) than younger adults.

In contrast, several studies have failed to support the relation between falling and age. Lipsitz et al. (1991) studied 70 fallers and 56 nonfallers in a nursing home and found no significant difference in age between fallers and nonfallers. Similarly, Morse et al. (1987) did not find age to be a risk factor for classifying fallers and nonfallers. Van Dijk et al. (1993) found no relationship between fall rates and age among older adults with dementia. In a study of 306 community-dwelling adults aged 70-years and older, Studenski et al. (1994) found no significant age difference between fallers and nonfallers. Moreover, Rosen, Campbell, Villanueva, and Morgan (1985) found the mean age between nonfalling and falling community-dwelling residents age 70 or greater not statistically different. Mahoney et al. (1994) compared fallers and nonfallers after discharge from a community hospital and found no significant differences in age. Again, differences in subject pools complicate the interpretation of these results.

While age appears to influence risk of falling, other variables (e.g., health and mental status) often associated with aging may be more pertinent as moderator variables. These variables will be discussed later in the chapter. Carefully conducted studies, controlling for the presence of moderator variables, need to be conducted to determine the direct influence of age on falls.

7.16.4.3.3 Race

Tentative findings suggest that race is also associated with the risk of falling. Specifically, Wofford et al. (1994) and Nevitt et al. (1989, 1991) found that Caucasians have a higher risk of falling and requiring EMS transport following a fall than African-Americans. Further studies of the relations between falls and ethnic and racial variables are needed. The falls literature has not addressed racial and ethnic group differences. The relations found between falling and these demographic variables should be interpreted with care because of possible differences in the reporting of falls by the different groups. Many variables may influence the reporting of falls and these issues need to be addressed.

7.16.4.4 Sensory Impairments

Impairments of vision, the vestibular system, and the somatosensory system can contribute directly and indirectly to falls. For example, visual impairments can preclude the detection of obstacles that may lead to a fall. Inaccurate or inadequate visual or proprioceptive information or a malfunctioning vestibular system can all lead to gait or balance problems. Attenuated sensations of touch and pressure on the bottom of the feet (sometimes due to peripheral neuropathy secondary to diabetes mellitus) can contribute to poor control of balance during stance and gait. The ability of the somatosensory system to function properly declines with age, as does the ability of the sensory-motor system after age 55 (Lord, 1996) and the ability to correctly register joint movement and position (Simoneau & Lebowitz, 1996). On a more positive note, good vision can sometimes compensate for other sensory deficits (Whipple, Wolfson, Derby, Singh, & Tobin, 1993).

The few studies that have examined the relationship between sensory impairment and falls have produced inconsistent findings. Mahoney et al. (1994) compared fallers and nonfallers with regard to visual impairments and found a significantly higher rate of visual impairment among fallers. Similarly, Granek et al. (1987) found a significantly higher rate of falls among blind than sighted individuals. Nevitt et al. (1989) found both decreased visual acuity and depth perception to place individuals at increased risk of multiple falls. Similarly, Felson et al. (1989) found a relationship between risk of hip fracture and poor visual acuity. Interestingly, they also found that older adults with good vision in one eye and moderately good vision in the other had an increased risk of hip fracture. Lord (1996) suggests that this could be due to poor stereoscopic vision that, in turn, reduces depth perception and increases fall risk. Lord (1996) concluded from his studies that contrast sensitivity, “detection of large visual stimuli under low contrast conditions,” is more important than visual acuity in predicting falls. The significance of these findings is particularly important when one considers that contrast sensitivity is essential for detecting edges, such as steps and misalignments of walking surfaces.

In contrast to the foregoing findings, Morse et al. (1987) found no significant differences between fallers and nonfallers with regard to visual impairments or hearing deficits. Similarly, Brocklehurst, Robertson, and James-Groom (1982) and Robbins et al. (1989a, 1989b) found no relation between visual acuity and falls among older adults beyond the age of 65. Though a comparison of findings regarding vision and falls is precluded due to methodological differences among studies, it is clear that the majority of studies suggest a relationship between falls and various measures of vision. More comparative studies utilizing similar subject populations and methodologies are sorely needed.

7.16.4.5 Muscle Weakness

The musculoskeletal system is essential for maintaining postural control and movement through the environment. Declines in muscle mass begin at approximately 25 years of age.

Muscle strength losses of 10–20% occur between the ages of 40 and 70, with losses of 30–40% occurring between the ages of 70 and 80 (Whitbourne, in press). The greatest declines in muscle strength in later years occur in muscle groups of the lower extremities, including the muscle groups involved in ambulation, transferring to and from seated positions, and climbing stairs.

Several studies have found hip and lower extremity muscle weakness to be related to falls (e.g., Campbell et al.,1989; Lipsitz et al., 1991; Robbins et al., 1989a, 1989b; Whipple, Wolfson,& Amerman, 1987; Wolfson, Judge, Whipple, & King, 1995). For example, Campbell et al., in a one-year prospective study, examined multiple risk factors for falling among community-based older adults. Female fallers had significantly less leg strength than female nonfallers, with a relative risk factor of 1.6. No differences were found in muscle strength between male fallers and nonfallers. Robbins et al. (1989) also examined multiple risk factors using both community-dwelling and institutionalized older adults. Hip weakness was one of the three risk factors identified. This risk factor yielded a 68% chance of falling within a one-year period, those without this risk factor had a 19% chance of falling within the same time period. Knee and ankle weakness have been found significantly more prevalent among fallers than nonfallers (Whipple et al.). Similarly, Wolfson et al. found that residents of a nursing home with histories of falls had less than half of the knee and ankle strength of nonfallers.

In summary, muscle weakness in the lower extremities is consistently found to be a risk factor for falling. This relation, however, may not always be direct since muscle strength is associated with a variety of other risk factors (e.g., gait, balance, speed). Fortunately, as later noted, muscle strength training can contribute to a decrease in falls.

7.16.4.6 Gait

Gait reflects the characteristics of a person's walking, which is controlled and influenced by a multitude of factors. Moreover, gait is a multidimensional construct that is measured in a variety of ways (see Duncan & Studenski, 1994, for a review). Disorders of gait affect 20–50% of older adults (Sudarsky, 1990). Impaired gait is considered to be a major contributor to falls, which can also contribute to negative psychological consequences (e.g., fear of falling) and the concomitants of fear previously discussed (e.g., immobility, further functional decline).

Numerous studies have found a relation between gait problems and falls. Morse et al. (1987), for example, found a greater percentage of gait problems among fallers (88%) than nonfallers (43%). Tinetti et al. (1988) found community-dwelling adults with balance and gait abnormalities to be as much as 1.9 times as likely to fall as those without these problems. Whipple et al. (1987) found fallers to have significantly slower gait speed and shorter stride length than nonfallers in a nursing home population. Also, Guimaraes and Isaacs (1980) found that fallers displayed slower walking speeds, shorter step length, and greater variability in their step length than nonfallers. Similarly, Wolfson, Whipple, Amerman, and Tobin (1990) revealed that fallers in nursing homes differed from nonfallers with regard to stride length and walking speed. Overall, studies of gait have found a high prevalence of gait disorders among older adults, placing them at significant risk of falling.

7.16.4.7 Balance

A balanced position requires the coordination and muscular control of individual body parts. Walking has been characterized as successive loss of balance episodes in which a fall is averted with each step by repositioning each foot (Simoneau & Leibowitz, 1996). Such postural control results from the coordination of sensory and musculo-skeletal systems. The ability to transfer from bed to floor, walk, and be seated requires balance obtained through these systems and their coordination. Therefore, problems with these systems can result in a loss of righting reflexes and an increase in body sway (Kay & Tideiksaar, 1990), leading to falls.

Poor control of posture (postural dyscontrol), as evidenced by poor balance, has been associated with falls for both community-dwelling and institutionalized older adults. Wild et al. (1981), as cited in Funk, Tornquist, Champagne and Wiese (1992), found that postural dyscontrol among community-dwelling older adults contributed to at least 67% of falls. In a prospective study of falls, Tinetti, Williams, and Mayewski (1986) found that residents recently admitted to an intermediate care facility with balance impairment were 5.4 times as likely to fall as those without a balance impairment. Similarly, Lipsitz et al. (1991), in a retrospective study of 126 nursing home residents, found subjects with a balance impairment to be 3.9 times as likely to fall as those without such an impairment. Tinetti et al. (1988), in a prospective study of community-dwelling adults 75 years of age and older, found that individuals with abnormalities of balance were 1.9 times as likely to fall when compared with individuals without such abnormalities. In a study of institutionalized and noninstitutionalized older adults, Robbins et al. (1989a, 1989b) found that fallers were significantly more likely than nonfallers to have impaired gait and balance. Balance was one of three risk factors that significantly and independently predicted falling among both populations.

Older adults may not lose their balance more often than younger individuals, but are simply less capable of correcting the imbalance (Overstall, 1992). One of the principal indices of imbalance is body sway. With increasing age there is a slowing of the ability to detect changes in posture or sway, which is associated with greater risk of falling. Brocklehurst et al. (1982) found a relation between postural sway, decreased proprioception, and falls. Similarly, Wild et al. (1981) found a relation between responses to pressure applied to the sternum (balance response) and risk of future falls. Several other studies have reported differences between fallers and nonfallers with regard to postural sway or unsteadiness (e.g., Lichtenstein, Burager, Shields, & Shiari, 1990; Overstall, Exton-Smith, & Johnson, 1977; Wolfson, Whipple, Amerman, & Kleinberg, 1986). Balance and gait tests have also been found useful in discriminating between residents of intermediate care facilities who fell two or more times from those who fell once or never fell (Tinetti et al., 1986). The findings of Tinetti et al. are particularly interesting because the situations in which balance was measured were those for which balance is particularly important (e.g., when rising, sitting, and turning around). Overall, the results of numerous studies suggest that poor balance, which increases with age, is a potentially significant risk factor for falls.

7.16.4.8 Medications

Medications have often been examined as potential factors influencing falls. However, research into the effects of drugs on fall rates is equivocal. Many studies have found that drugs influence fall risk (Cooper, 1994; Lipsitz et al., 1991; Tinetti et al., 1986), while others have found no significant effect of drugs on fall risk (Lord, Clark, & Webster, 1991; Mahoney et al., 1994; Morris, Rubin, Morris, & Mandel, 1987; Tinetti, 1987). Total number of medications taken (Lipsitz et al.; Robbins et al., 1989a, 1989b; Studenski et al., 1994), addition of a new medication (Tinetti et al., 1986), and recency of drug administration (Aisen, Deluca, & Lawlor, 1992; Lipsitz et al.; Nevitt et al., 1989) have all been associated with falls. Further, the use of more than six medications was associated with the inability to get up following a fall (Tinetti et al., 1993). Methodological differences between studies may explain disparate results. Drug variables entered into data analysis differ greatly between studies. Many studies group all drug classes together within a single category while others examine specific classes of drugs. While many studies fail to find a relation between a global medication measure and falls, the influence of particular classes of drugs have been found to influence fall risk. For example, antidepressants have been identified as a risk factor for further falls (Lipsitz et al.). In addition, there may be gender differences in drug influences on falls. Cambell et al. (1989) found the total number of drugs taken to influence fall rates among women but not among men.

Specific classes of drugs influence the risk of falls. Drugs directly influencing cognitive states or alertness may increase the risk of falling. For example, Quail (1994) found alcohol to be related to the occurrence of falls. Side effects of drugs also influence the risk of falling. For example, Downton and Andrews (1990) found sedatives associated with subjective reports of dizziness, which is related to increased risk of falling. Drug classes which have been investigated in the literature include antidepressants, sedative/hypnotics, anti-inflammatories and analgesics, cardiovascular agents, neuroleptic/antipsychotics, antihistamines/anticholinergics, antidiabetics, diuretics, anticonvulsants, nitrates, and anti-Parkinsonian medications. Several of these will be discussed in detail below. As new medications are introduced and utilized in the older adult population, the influence of medications on fall risk needs to be reevaluated.

7.16.4.8.1 Antidepressants

Antidepressants are utilized for their ability to elevate mood and increase energy. As with all the drug classes, research on antidepressants has produced mixed results. Antidepressant use has been associated with increased risk of falling among nursing home residents (Lipsitz et al., 1991), recurrent falls in long-term care patients (Luukinen et al., 1995), and distinguished between fallers and nonfallers among community-dwelling males and nursing home residents (Studenski et al., 1994; Lipsitz et al.). Moreover, it has been associated with decreased risk of falls in community-dwelling psychogeriatric patients (Asada et al., 1994). In contrast, other researchers have not found antidepressant use to be associated with falls among residents of homes for the elderly (Graffmans et al., 1996) or community-dwelling older adults (Nevitt et al., 1989). Differences in results may be attributable to differing classes of antidepressants.

Three major types of antidepressant are prescribed: tricyclics, monoamine oxidase inhibitors (MAOI), and selective serotonin reuptake inhibitors (SSRI). Each class will be discussed separately due to their various effect and side effect profiles. While each drug produces numerous side effects, only those relevant to falling will be mentioned. The exact mechanism by which tricyclic antidepressants produce their antidepressant effect is unknown but it is assumed that they block the reuptake of norepinephrine, dopamine, and/or serotonin. Tricyclics may produce orthostatic hypotension, heart palpitations, tremor, sedation, and delirium. Research into tricyclic antidepressants and falling is equivocal. Quail (1994) reported that tricyclics increased the risk of falling in an outpatient population, especially when they were combined with other drugs. In contrast, Mahoney et al. (1994) found no significant effect of tricyclics among discharged hospital patients. While no research has been conducted on MAOIs and SSRIs, they are important to mention due to their possible relation to falls. Both produce anticholinergic side effects such as dizziness, blurred vision, or nausea which can influence the possibility of falls. More research into the exact types of antidepressants producing positive relations with falling is needed to determine the risk of prescribing these drugs to the elderly.

7.16.4.8.2 Sedatives/hypnotics/anxiolytics

Sedatives/hypnotics are typically prescribed as sleep aids or calming agents. They may also be prescribed as anticonvulsants. However, they can have serious side effects including disrupted sleep patterns, confusion, light-headedness, and drowsiness. Sedatives have also been associated with subjective dizziness in community-dwelling older adults (Downton & Andrews, 1990). Sedative use has been associated with falls in community-dwelling older adults (Tinetti et al., 1988, 1993), recurrent falls of these individuals (Nevitt et al., 1989), and the inability of these individuals to get up following a fall (Tinetti et al., 1993). While a relationship has been found between sedative/hypnotic use among women (Campbell et al., 1989), many studies have failed to find a relation between falls and sedative/hypnotic use in male community-dwelling older adults (Studenski et al., 1994), ambulatory nursing home residents (Lipsitz et al., 1991), or community-dwelling psychogeriatric patients (Asada et al., 1994). The relation between alcohol use and falls has been unclear in the literature. Campbell et al. and Nevitt et al. (1989) found no relation between alcohol and falls in community-dwelling older adults, while Quail (1994) found alcohol to be related to falls among outpatients. Similar to research findings regarding antidepressants, disparate results may be attributable to different specific drugs within the classes. However, it is also possible that drugs are exacting different effects on different subjects.

Anxiolytics, of which the most common class is benzodiazepines, are utilized to reduce anxiety symptoms. Unfortunately, they are also addictive and can be fatal in high doses. No relation between benzodiazepines and falls in community-dwelling males (Studenski et al., 1994), residents of homes for the elderly (Graafmans et al., 1996), or discharged hospital patients (Mahoney et al., 1994) has been found. However, Aisen et al. (1992) found that PRN administration of benzodiazepines was two times more frequent in fallers. Moreover, in 24 of 33 falls among inpatient geropsychiatric patients, benzodiazepines were administered within 24 hours of the occurrence of a fall.

7.16.4.8.3 Neuroleptics/antipsychotics

Neuroleptics are sometimes referred to as the major tranquilizers due to their heavy sedating effect in high doses. Typically, they are prescribed for the treatment of psychotic disorders or agitation in elderly patients. They can result in extrapyramidal effects and blurred vision, both of which can increase the risk of falling. Brown and Edelstein (1995) found that the use of antipsychotic medications significantly increased the risk of falls among psychogeriatric inpatients. Lord, McLean, and Stathers (1992) found similar results with antipsychotic use being a significant risk factor for falls among community-dwelling older adults. Quail (1994) found similar results among outpatients with the use of major tranquilizers increasing the risk of falling by 50%. In contrast, Lipsitz et al. (1991) found no relation between antipsychotics and falls in ambulatory nursing home residents. Moreover, no relation was found between antipsychotics and falls among community-dwelling psychogeriatric patients (Asada et al., 1994) or discharged hospital patients (Mahoney et al., 1994).

7.16.4.8.4 Cardiovascular medications

Although a large portion of older adults are prescribed cardiovascular medications, very little research has been conducted on their relation to fall among older adults. Graafmans et al. (1996) is the only study which has found a positive relation between a type of cardiac medication, peripheral vasodilator, and the recurrence of falls. Cardiac medications were not associated with falls in nursing home or community-dwelling older adults (Robbins et al., 1989a, 1989b), psychogeriatric patients (Brown & Edelstein, 1995), or ambulatory nursing home patients (Lipsitz et al., 1991). Moreover, although antihypertensives led to severe postural symptoms among outpatients, they were not associated with falls (Graafmans et al.; Quail, 1994). Finally, diuretics, digitalis, and vasodilator were not significantly related to falls among long-term care patients (Luukinen et al., 1995).

7.16.4.8.5 Analgesics and anti-inflammatory medications

Medicines prescribed for the alleviation of pain or inflammation are often prescribed to older adults. In a study of ambulatory nursing home residents, fallers were significantly more likely than nonfallers to be taking analgesics (Lipsitz et al., 1991). However, the taking of analgesics was not found to be significantly related to falls among psychogeriatric inpatients (Brown & Edelstein, 1995) or residents of homes for the elderly (Graafmans et al., 1996). Ingestion of anti-inflammatory medications has not been found to be significantly related to falls among nursing home residents (Graffmans et al.; Lipsitz et al.).

The previous discussions regarding drugs demonstrate the need for research examining the relation between drugs and falls. Although some classes of drugs have been identified as potentially increasing the risk of falling, drug interactions may also account for increased fall rates. The majority of research on drugs has involved retrospective reviews. Unfortunately, very few subjects are prescribed only one drug. Therefore, differing results may be due to drug interactions. For example, a person taking an antidepressant may not be at increased risk of falling but an individual taking an antidepressant and a cardiovascular medication may be at increased risk. Medications have multiple effects on many systems within the body. It is likely that individual differences account for differential drug effects. The complex interplay of drugs and physiological systems requires more knowledge.

7.16.4.9 Medical Disorders

The relationship between the type of medical disorder and fall risk is unclear, as studies have yielded mixed results. Numerous studies have found relations between falls and underlying medical diseases (e.g., Campbell et al., 1990; Nevitt et al., 1989; Rubenstein et al., 1990). Rubenstein et al., following their review of several falls studies, estimated that 55% of falls are related to medical disorders, with the greatest percentage of these being due to chronic diseases. Among the disorders related to falls are arthritis of the knee, stroke (Campbell et al.,1989), Parkinson's disease (Davie, Blumenthal, & Robinson-Hawkins, 1981; Studenski et al, 1994), osteoarthritis, unspecified arthritis (Davie et al.), diabetes, and hypotension (Davie et al.; Lipsitz et al., 1991). Though considerable support has been found for relations between medical disorders and falls, several studies have failed to find this relation for some of the same disorders (e.g.,Lipsitz et al.; Morse et al., 1987; Studenski et al.). Brown and Edelstein (1995) noted that the only apparently consistent finding in this literature is the strong relation between musculoskeletal disorders and falling.

The mostly mixed and contradictory findings noted above are likely attributable to differences in numerous factors across studies (e.g., subject population, physical and mental status, age, nature and number of diseases, research procedures, length or severity of disorder) that can directly or indirectly influence reported fall rates. For example, Lipsitz et al. (1991) based their fall rate on falls witnessed by staff or self-reported by nursing home residents. In contrast, Davie et al. (1981) and Studenski et al. (1994) obtained data via telephone calls and interviews of community-dwelling adults. Davie et al. may have obtained results different from Lipsitz et al. and Morse et al. (1987) regarding falls among individuals with diabetes or hypotension because of participant differences. Davie et al. studied community-dwelling residents, whereas Lipsitz et al. and Morse et al. studied inpatients. Hospitalized older adults are generally at a greater risk of falling than community-dwelling adults, as they tend to be more cognitively impaired and less ambulatory. In conclusion, it may be naive to believe that the effects of individual medical conditions can be isolated and that findings across studies can be compared. It is not uncommon for older adults to simultaneously experience multiple medical disorders. When considering the problems of matching participants across studies on the many factors believed to be related to falls, the prospect of obtaining reliable results appears improbable.

The relationship between the number of medical disorders and fall risk also remains unclear. Studies by Kalchthaler et al. (1978) and Morse et al. (1987) found a positive relationship between number of medical disorders and falls.

Kalchthaler et al. found the largest number of falls among nursing home residents with three to six medical disorders. Similarly, Morse et al. found fallers had significantly more medical disorders than nonfallers. Although the medical disorder in fall literature is fraught with inconsistencies in methodologies and results, there is certainly sufficient support for the contention that medical disorders, particularly those of a chronic nature, place older adults at risk of falls.

7.16.4.10 Psychiatric Disorders

The effects of psychiatric disorders are difficult to separate from their treatment (e.g., psychotropic medications), the overall mental status of the participants, and the setting in which falls are examined. Institutionalized individuals are generally more likely to suffer from psychiatric disorders, be receiving psychotropic medications, and have poorer mental status than individuals still living in the community. In addition, they are more likely to fall. A small number of researchers have examined the relationship between psychiatric disorders and falls, some of which have found support for such a relationship. Hernandez and Miller (1986), for example, examined fallers on a psychogeriatric unit and found fallers to have the following psychiatric diagnoses: dementia (77%), depression (43%), and agitation or paranoia (21%). Similarly, Poster et al. (1991) found older adults in a psychiatric hospital with psychotic disorders to be at greater risk of falling than those without psychotic disorders. Granek et al. (1987) found significantly more depressed fallers than nonfallers in a long-term care facility.

Similar findings have been revealed among community-dwelling adults. Davie et al. (1981) found the presence of a psychiatric diagnosis to be related to falling among community-dwelling older adults. Similarly, Asada et al. (1994) found depressed community-dwelling individuals at a significantly greater fall risk than nondepressed individuals.

In contrast to the foregoing results, several studies have failed to find positive relations between psychiatric disorders and falls. For example, Hernandez and Miller (1986) and Granek et al. (1987) found no significant differences in the incidences of Parkinson's disease between fallers and nonfallers. Brown and Edelstein (1995) also found no relation between psychiatric disorders and falling. Moreover, there have been a few studies suggesting a possible protective effect of psychiatric disorders. For example, Poster et al. (1991) found patients with Bipolar Disorder to be at lower risk of falling than other patients. The only apparently consistent finding across several studies is the positive relation between depression and falling. Unfortunately, it cannot be determined whether this is primarily due to the disorder, cognitive deficits resulting from the disorder, the medications used to treat the disorder, or some combination of these and other factors that could serve to moderate this relationship.

In conclusion, there appear to be few intrinsic factors that reliably predict falls. However, a few factors have emerged as predictors in a sufficient number of studies to certainly warrant further investigation and exploration in prevention programs, particularly with regard to the type of intervention that is most effective for each particular risk factor.

7.16.5 PREVENTION OF FALLS

While the prevention of all falls is virtually impossible, numerous authors have offered suggestions for the development of prevention programs and limited empirical support has been found for some prevention practices. Recommendations for fall prevention have typically been based upon "common sense" (Gibson et al., 1987) and identified risk factors. However, Rubenstein and Josephson (1993) have aptly noted that while the literature is replete with such recommendations for preventing falls, few of the recommendations are based upon sound, controlled research. Similarly, Tinetti (1994) argued that fall prevention "studies reported in the literature to date have shown either no or only marginal reduction in fall rate" (p. 758). However, there has been evidence of successful prevention programming. In the following section approaches to prevention will be discussed and a few of the more promising studies published will be reviewed.

Falls can have multiple causes that vary across individuals. Thus, effective fall prevention programs must take into consideration a myriad of potential risk factors for each individual. Prevention programs might include risk factor identification, assessment following falls, exercise programs, alarm systems, and protective devices (Rubenstein & Josephson, 1993). Because the prevention programs often contain multiple interventions, it is difficult to compare studies in any meaningful way. Nevertheless, an attempt will be made to consider elements of prevention programs by following Tideiksaar's (1993a) categorization of prevention strategies, which include medical, rehabilitative, and environmental interventions.

7.16.5.1 Medical Prevention Strategies

Medical prevention strategies typically address risk factors through an initial risk factor assessment that might include mental status examination (to assess for delirium, dementia, depression), postural blood pressure measurement (to test for orthostatic hypotension), cardiac evaluation (to check for arrhythmias, valvular disorders), neurological evaluation, mobility assessment (e.g., ambulation, transfer from chair, bed or toilet), visual acuity testing, lower extremity muscle testing, balance testing (e.g., postural stress test), gait testing (e.g., Gait Abnormality Rating Scale), functional status evaluations, and a review of medications (Rubenstein & Josephson, 1993; Tideiksaar, 1993a). While many of these "conditions" cannot be prevented, many can be treated successfully, thereby reducing fall risk. In some cases the impact of these factors can be attenuated. For example, improved prescription practices (e.g., appropriate medication use, limiting number of medications, attention to drug interaction effects) can reduce fall rate. Several researchers have explored the effects of improving prescription practices. Goals included the reduction in amount of medication taken, reduction in the use of sedatives (particularly long-acting sedatives), and reduction in the use of tranquilizers. Rane-Szostak (cited in Gibson et al., 1987) attempted to reduce the number of falls in a large rehabilitation-oriented nursing home by asking physicians to reduce the use of sedatives (particularly long-acting sedatives) and tranquilizers. Nurses offered alternatives to medication for sleep, including changes in bedtime routines, using mild analgesics for pain, and providing evening snacks. A 70% reduction in the number of fall-related fractures has been attributed to the decreased use of sedatives and tranquilizers.

Once a fall has occurred, a detailed description of the circumstances surrounding the fall is recommended. The medically-oriented questions address such factors as loss of balance, dizziness, and other medically-related symptoms that have preceded the fall. The results of these inquiries can then be used in the development of prevention programs.

Tideiksaar (1993a) also suggested that these same questions following near-falls be explored. A near-fall involves a loss of balance without the occurrence of a fall due to gaining support from the environment (e.g., grabbing a hand rail). Near-falls are important to explore as they appear to portend future falls and may involve many of the same risk factors. Knowledge of these factors can be incorporated into prevention programs that could preclude or at least reduce the likelihood of future falls.

7.16.5.2 Rehabilitative Strategies

Fall risk can potentially be reduced through a variety of rehabilitative strategies. These might include muscle strengthening exercises, balance and gait training, and training in the proper use of ambulatory assistive devices. As previously noted, the relationship between lower extremity muscular strength and falls is quite strong. Weakened muscular strength can affect gait and balance, all of which can contribute to falling and fear of falling. Numerous studies have focused on increasing muscle strength with the goal of improving joint flexibility, gait, and balance (e.g., Fiatarone et al., 1994; Province et al., 1995). Such programs can include resistance exercises, weight-lifting, and leg stretching exercises. Flexibility and balance training, and even Tai Chi exercises, have shown positive results through improved gait and balance (e.g., Province et al.). Fiatarone et al. increased muscle strength by 113%, yielding a 12% increase in walking speed and a 28% increase in stair climbing ability through progressive resistance training among frail nursing home residents with a mean age of 87 years. Promising results have also been reported by Wolf, Kutner, Green, and McNeely (1993), who conducted a prospective, randomized controlled clinical trial comparing the effects of Tai Chi and computerized balance training with community-dwelling older adults. By 15 weeks, participants in the Tai Chi course reduced their fall rates by 47%, although the risk of falling was actually higher for those Tai Chi participants that experienced falls within the previous year. Fear of falling also decreased in the Tai Chi group.

7.16.5.3 Environmental Strategies

Environmental approaches to reduce fall risk attempt to do so by modifying the physical environment. Falls occur when there is a mismatch between an individual's performance level and the performance demands of environmental tasks (Hogue, 1992). Although physically fit individuals can lose their balance and fall, very frail individuals are probably the most dependent upon the environment to support the performance of tasks (Hogue, 1982, 1991; Waller, 1978). Frail individuals "may be unable to maintain postural control (prevent a fall) with virtually no external provocation" (Hogue, 1992, p. 45). The physical environment can often be modified to accommodate individuals whose abilities do not match the current environment. For example, higher seated chairs and toilets can replace lower seated ones to reduce the demands of transfer. Lighting can be intensified to reduce the risk of falls resulting from poorly illuminated areas, nonskid floor surfaces can replace slippery surfaces, stairways can be equipped with handrails for support, grab bars can be placed near toilets, bathtubs, and showers for support during transfers, and objects situated around the living environment that block or obstruct walk areas can be moved.

Tideiksaar (1997) noted that there is no definitive evidence of the efficacy of these environmental modifications in reducing falls. However, a few studies have offered promising results. Tideiksaar (1990), as reported in Tideiksaar (1997), eliminated various environmental hazards in the homes of older adults with multiple slip and trip falls. Slippery and irregular ground surfaces in the home were modified resulting in a decrease in number of falls over the following year.

Taking a more comprehensive approach, Wolf-Klein et al. (1988) provided medical management, home visits, and a falls prevention educational program for the participants in their study and their families, yielding a significant decrease in falls over the following year. Such comprehensive approaches have also been successful in institutional settings (e.g., Heslin et al., 1992; Hollinger & Patterson, 1992). Heslin et al. identified fall risk factors in acute, long-term, and residential health care settings and developed prevention strategies for each setting. Participants included 581 acute, 138 long-term care, and 247 residential care patients in a 966-bed teaching hospital. Fall rates at the beginning of the study were 2.16% for acute care, 1.46% for long-term care, and 9.38% for residential care. All but 17% of the fallers were 60 years of age or older. Prevention interventions targeted specific care settings and types of falls. Prevention in the acute care setting was directed at falls related to beds. The program included a fall risk assessment, nursing care plan, spot-the-dot (color-coded markers placed in risk areas), and bed sensors to alert staff to movement from beds. The number of bed-based falls decreased significantly (85%) over a three-month period using the sensor system. The spot-the-dot procedure was completely successful, with no bed-based falls following initial adjustments to the program on a medical unit. The long-term care interventions yielded similarly successful outcomes, with bed falls and transfers being targeted for interventions. When Huntington's Chorea patients who had experienced falls from bed had their restraints removed, their bed rails padded with cushions, and the bed surrounded with mattresses, injuries were reduced to zero. Bed to chair transfers, which account for approximately 50% of bed-based falls in the long-term care setting, were reduced by 92% through changes in transfer procedures and transfer devices.

Hollinger and Patterson (1992) developed and evaluated a falls precaution assessment and prevention program in an acute care setting. All participants were evaluated initially with a Fall Assessment Tool that addressed patient and environmental factors known to be risk factors for falling. Individualized prevention programs were then developed for individual patients based upon the findings with the Fall Assessment Tool. These programs included such precautions as use of assistive devices, night lights, and nonskid footwear. The fall rate over a six-month period was reduced significantly from a preintervention mean of 4.06 to a postintervention mean of 2.63.

7.16.5.4 Combined Prevention Strategies

Many of the reported prevention studies have employed a variety of intervention methods that involved medical, environmental, and rehabilitative approaches or some combination of two or more of these. For example, Tinetti et al. (1994) examined the effects of three different interventions with 301 men and women living in the community. All participants were at least 70 years of age and had at least one of the following risk factors: "postural hypotension; use of sedatives; use of at least four prescription medications; and impairment in arm or leg strength or range of motion, balance, ability to move safely from bed to chair or to the bathtub or toilet (transfer skills), or gait" (Tinetti et al., 1994, p. 821). The interventions were either usual health care or the combination of medication adjustment, behavioral change recommendations, and home-based exercise programs. Participants were followed for one year, during which 35% of the intervention group and 47% of the control group fell. The authors also demonstrated significant reduction in risk factors among the intervention group.

Although a broad range of prevention programs have been implemented, they have yielded mixed results. As Tinetti (1994) noted, the handful of clinical trials conducted prior to 1994 had somewhat discouraging results (see Hornbrook et al., 1994; Mulrow et al., 1994; Reinsch, MacRae, Lachenbruch, & Tobis, 1992; Rubenstein et al., 1990; Rubenstein, Robbins, & Josephson, 1991; Vetter, Lewis, & Ford, 1992). The recent "Frailty and Injuries:

Cooperative Studies of Intervention Techniques" (FICSIT) trials, however, offer more promising data from a large series of clinical trials (e.g., Tinetti, Baker et al., 1994; Wolf et al., 1993). Moreover, if empirical studies that do not meet the criteria for "prospective, controlled trials" are considered, the evidence in support of prevention programs is even more encouraging.

Perhaps what is most discouraging about the prevention literature is the failure to identify interventions that reliably reduce fall frequency or severity. Researchers may be at the point in prevention research that they must match interventions to the participants, with the hope of establishing which interventions are most effective with participants with particular characteristics and risk factors. Similarly, more effective prevention programs may be developed by considering such factors as whether the potential fallers are at little or great risk of falling, with different preventive approaches being most effective with one or the other of these two groups (Gibson et al., 1987). Perhaps attention should be focused on the prevention of particular types of falls. Tinetti (1994) has raised the provocative question of whether the goal of prevention programs should be the reduction in risk of all falls or the reduction in risk of injurious falls.

In conclusion, there is reason for optimism about the prevention of falls. Researchers have identified factors that place older adults at risk, have demonstrated that some of these factors can be changed through a variety of interventions, and have begun to demonstrate that some prevention programs can be effective with some individuals. The optimal approach for individuals with particular characteristics experiencing particular types of falls remains to be determined.

7.16.6 SUMMARY

This chapter has provided an overview of the empirical literature on falls among older adults. It began with considerations of conceptual and methodological issues, including how falls are conceptualized and measured. The many consequences of falls, including physical, medical, psychological, and economic consequences, were then discussed. Numerous intrinsic and extrinsic risk factors for falls were then considered, followed by a discussion of prevention approaches based upon these risk factors. Finally, the chapter concluded with a cautiously optimistic view of the prevention literature, suggesting that future preventive efforts focus on optimal matches of prevention programs to individual faller characteristics.

7.17.1 WANDERING: A MODEL CASE

Mrs. G. walks intently toward the dining hall of the nursing home, a purse draped over her arm and golf hat sitting slightly askew atop her graying hair. When asked of her destination, she talks pleasantly in partial sentences of a luncheon date at the club. Mrs. G. enters the dining area and paces back and forth in front of a windowed wall overlooking a grassy courtyard. Appearing upset at times, she repeatedly attempts to slide the glass panels open. Passersby can hear her express determination to meet her husband, now long deceased, and observe her distress about his "overdue" arrival.

Most clinicians providing long-term care to cognitively-impaired persons encounter behavior such as this and call it wandering. Compared to its frequency in the clinical setting, the number of articles and studies of this behavior is small. Wandering has generally been viewed as an accompaniment to dementia or, worse, is seen as a nuisance. Perhaps its very commonness has worked against serious investigation of the phenomenon until the past decade.

This chapter presents a comprehensive review of the research and clinical literature on wandering. Sections addressing definitions and typologies, epidemiological data, putative risk factors and outcomes, etiologic factors and theories, assessment, and intervention are offered. Throughout each section, findings are summarized, gaps identified, suggestions for further research offered, and implications for clinical practice identified.

7.17.2 DEFINITIONS AND TYPOLOGIES OF WANDERING

Despite increasing interest in this perplexing behavior, the term "wandering" lacks a consistent meaning. Multiple definitions have been proposed from the clinical, conceptual, and empirical viewpoints of several disciplines, most notably psychology, nursing, and social work. Some definitions aim for objectivity while others impute a basis or cause for the behavior. Similarly, some attempt to circumscribe or limit the meaning to a narrow range of behavior while others use it loosely to include behaviors that accompany wandering, such as requests to leave, or are consequences of it, such as eloping or absconding from an expected or authorized area. The only universals in various characterizations of wandering discussed in this chapter are the presence of cognitive impairment and movement through large-scale space.

The term "wanderer" has also been applied to sleepwalkers (nocturnal wanderers) (Guilleminault, Kushida, & Leger, 1995; Guilleminault, Moscovitch, & Leger, 1995; Kushida, Clerk, Kirsch, Hotsin, & Guilleminault, 1995; Plazzi, Tinuper, Montague, Provini, & Lugaresi, 1995), vagrants (Weller & Jauhar, 1987), and patients who switch repeatedly from one physician to another (Pankratz & Jackson, 1994). These meanings of wandering are excluded from this review.

7.17.2.1 Clinical Views

Wandering poses a quandary for clinicians, inducing a conflict between the goals of affording both maximum freedom and safety for the afflicted. Consequently, clinicians usually advocate for a humane and tolerant approach to the behavior within a protected area. However, their definitions of wandering are among the most broad and imprecise and, thus, may inadvertently result in restriction of those whose ambulation poses no threat of harm. Coons (1988) defined wandering simply as self-initiated ambulation occurring independently of environmental cues to move, such as a ringing dinner bell or an invitation to an activity by a caretaker. While objective in that it is observable and infers no specific cause, Coons' definition is not particularly useful since virtually all spontaneous ambulation of cognitively-impaired individuals is included. In an early effort to clarify the behavior, Rader, Doan, and Schwab (1985) identified wandering as one end of a continuum of behaviors reflecting some effort to fulfill a social, emotional, or physical agenda or need that may or may not be rooted in current reality. While useful for pointing to possible constructive avenues for intervention, this definition fails to differentiate harmless from worrisome wandering and, thus, offers no clear guide for when to intervene.

7.17.2.2 Conceptual Schemes and Typologies

In efforts to more clearly delineate the behavior and explicate possible explanations for it, a number of others have taken more analytical approaches to defining wandering and classifying possible subtypes. Although data are offered in support of some of these typologies, most are more anecdotally than empirically derived.

Snyder, Rupprecht, Pyrek, Brekhus, and Moss (1978) defined wandering "as a tendency to move about, either in a seemingly aimless or disoriented fashion, or in pursuit of an indefinable or unobtainable goal" (p. 272). They also proposed the earliest typology of wandering based on chart reviews of eight nurse-identified wanderers. Three types were reported: (i) overtly goal-directed/searching behavior, associated with calling out repeatedly or approaching others in pursuit of a goal; (ii) overtly goal-directed/industrious behavior, typified by keeping busy with work-like actions, such as dusting; and (iii) apparently nongoal-directed behavior, described as ambulation that is aimless or shifts direction abruptly in response to changing environmental stimuli.

"Getting lost" or the inability to return to one's point of origin has also been suggested as a definition for wandering (Hussian, 1981, 1982). Greene, Smith, Gardiner, and Timbury (1982), who also equated wandering with getting lost, expanded this view by differentiating wandering types according to time of day (day or night) and location (outside vs. inside the home). However, wandering also entails a change in activity level that does not necessarily correlate with getting lost (Fairburn & Hope, 1988).

Based on observations of 13 residents in the geriatric unit of a state mental institution, Hussian and Davis (1985) proposed four independent types of wanderers: (i) akathesiacs, associated with extended hospitalization and long-term neuroleptic use and characterized by episodes of higher frequency and duration and lower attempts to leave or self-stimulate; (ii) exit seekers, associated with recent admission and characterized by frequent requests to leave, a high number and proportion of attempts to open exit (rather than other internal) doors, and a varied frequency and duration of ambulation episodes; (iii) modelers, who join with another ambulating resident and display little contact with door knobs, a low degree of self-stimulating behavior, and varying frequency and duration of episodes; and (iv) self-stimulators, who show other perseverative and stereotypical behaviors and no clear preference for exit doors. Analysis to support these categories was lacking.

More recently, a classification was proposed to differentiate dangerous from harmless wandering and to better target intervention strategies (Butler & Barnett, 1991). Based on the person's whereabouts and the patient's and nurse's knowledge of the same, four classes were delineated: purposeful (person and nurse know), escapist (person knows, nurse doesn't), aimless (nurse knows, person doesn't), and critical (neither know). While aimless wandering may be most stressful to caregivers, escapist and critical types are most dangerous due to associated elopements and injuries.

A time-in-motion approach was suggested to delineate wandering categories (Thomas, 1995). Continuous wanderers were said to be "moving constantly." Characteristics offered to describe this category included a higher level of cognitive impairment and inefficient travel behavior, a dissociation from feelings of fatigue or lack of awareness of the need to rest, and minimal social activity. On the other hand, sporadic wanderers move about occasionally. In addition to higher levels of cognitive function than continuous wanderers, sporadic wanderers were described as having greater ability to communicate verbally. While this classification scheme does reflect some clinically observed variations among wanderers also reported by others, Thomas used the cut-off point of 50% of time-in-motion to distinguish the category types without affording a rationale for this criterion.

One typology of wandering is clearly derived from an empirical base, where the travel patterns of wanderers ($n = 24$) and nonwanderers in a sample of 40 nursing home residents were evaluated (Martino-Saltzman, Blasch, Morris, & McNeal, 1991). Subjects' ambulation episodes occurring over a four-week period in pre-set locations were captured on videotape; 5768 events initiated without assistance of staff, visitors, or other residents were recorded. Each was described and then categorized by coders and the first author. Four patterns evolved: direct, travel between two points without diversion; pacing, repetitive back and forth travel within a limited area; lapping, repetitive travel encircling large areas; and random, haphazard travel between several locations without repetition. Coders achieved an acceptable inter-rater reliability (kappa = 0.79, $z = 13.2$, $p < 0.0001$) in a subsample of 231 events.

7.17.2.3 Empirically-based Descriptions and Features

Serious effort to evolve empirical descriptions and characterizations of wandering is limited to only a few recent studies. Two independent lines of research, differentiated by target population and methodology, are emerging. Although each approach has its limitations, these investigations are beginning to clarify what constitutes wandering behavior and to elucidate differences among wandering types.

Investigators in the UK are using community-based samples to uncover the inherent structure of wandering. Using a portion of the Present Behavioural Examination (Hope & Fairburn, 1992), a semistructured guide, they interviewed 29 caregivers of wanderers who were referred from the caseload of three community psychiatric nurses. The proportion of subjects showing each of the nine discrete behaviors at anytime since the onset of dementia was determined along with their gender, duration of dementia, and score on the Mini-Mental Status Examination (MMSE) (Folstein, Folstein, & McHugh, 1975). The following frequencies were reported: increased walking activity (17), wandering away from home (16), aimless walking (15), walking for an inappropriate purpose (14), checking/trailing (11), attempting to leave home (10), overactivity at night (9), pottering (6), and walking with appropriate purpose but an inappropriate frequency (4). No association with concomitant physical illness, medications, or premorbid activity levels was found. From these behaviors, a typology of wandering that could point to potential underlying etiologies was posed. These were: (i) increased overall walking activity, (ii) avoidance of being alone, (iii) diurnal rhythm disturbance, (iv) navigational problem, and (v) faulty goal-directed behavior (Hope & Fairburn, 1990). Although each subject exhibited more than one behavior, the time order of behaviors or any concurrent expression of them were not discussed. In a secondary analysis of the same data using Guttman scaling, Albert (1992) demonstrated that these nine behaviors were not a typology, but reflected a unidimensional hierarchical structure. Although the coefficient of reproducibility (0.78) fell slightly short of the 0.90 suggested by Guttman (1974), Albert argues that it is notable given the small sample size.

To challenge Albert's conclusion, Hope et al. (1994) conducted a factor analysis upon data from 83 subjects who were rated for 11 behaviors, that is, those listed earlier with the separation of checking/trailing and the addition of reduced walking. Only nine behaviors were used in analyses as wandering away from home and attempting to leave home did not correlate well with other behaviors. A four-factor solution explained 54.5% of the variance. Checking and trailing composed Factor 1, more and aimless walking constituted Factor 2, pottering stood alone as Factor 3, and inappropriate and overappropriate walking constituted Factor 4. Less walking and night-time walking did not load on any factor. In a scaling analysis of this data, neither the coefficients of reproducibility nor scalability were sufficient to support the conclusion of a hierarchical structure.

Investigators in the USA are using nursing home samples to describe various patterns of wandering in rhythmic terms (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997; Algase, Beattie, Kupferschmid, & Therrien, 1997; Algase & Cheng, 1992a; Algase & Tsai, 1991). In their first study, a descriptive survey design and cluster sampling were used to screen 31 wanderers from a larger sample of 198 ambulatory, cognitively-impaired persons from eight randomly selected nursing homes. Wandering was viewed as a nonlinear, ultradian, biphasic rhythm with locomoting and nonlocomoting phases. It was operationalized by counting and timing cycles and their locomoting phases; each cycle was coded for impetus (self- or other-directed), location, and activity at onset and cessation of the locomoting phase using stopwatches and paper–pencil coding techniques. Without a typology for differentiating wandering from other ambulating, self-initiated cycles with locomoting phases ending in activity other than self-care (e.g., toileting, eating) were considered wandering. In accord with then current views of wandering as being aimless activity, "purposeful" ambulation, such as going to the toilet, was not counted as wandering. Wanderers were observed 1:1 for two 24-hour periods one week apart by coders trained on videotapes to time cycles to within 10 seconds of each other (Algase & Cheng, 1992a; Algase & Tsai, 1991).

Subjects averaged 79.24 wandering cycles (range = 19.5–162; SD = 39.33) and 110.07 minutes of locomotion (range = 69.04–257.02; SD = 61.32) daily. A distinct 24-hour pattern for hourly cycle frequency and hourly sum of locomoting phase durations was also identified (Algase, 1992a; Algase & Cheng, 1992a; Algase & Tsai, 1991), with the period from 1400 to 1600 representing the period of greatest wandering by both parameters for the sample as a whole. Night-time wandering was minimal, averaging less than one cycle per hour per subject.

Repeated measures ANOVA demonstrated that cycle frequency, locomoting and nonlocomoting phase durations, and percent of cycle locomoting were stable over a one-week period with no day effect or day by hour interaction effects. However, there was a significant hour effect on all cycle variables (Algase & Cheng, 1992a; Algase & Struble, 1992; Algase & Tsai, 1991). Further analysis also demonstrated that, of four start and stop types, solitary/unfocused starts (52%) and stops (45%) were most common, while social/unfocused starts (5%) and stops (5%) were least likely. Though relatively rare, cycles with social/unfocused starts had longer locomoting phases ($F = 3.76$; $p = 0.01$) and a higher percent of cycle locomoting ($F = 3.25$; $p = 0.02$). Variability in cycle period and nonlocomoting phases by start type and in all cycle variables by stop type were not significant (Algase & Cheng, 1992b). Though measures for wandering were cutting edge at that time, distinctions between wandering and nonwandering were crude and no classification to distinguish among any subtypes was used.

In a subsequent study, Algase, Beattie, Kupferschmid, and Beel-Bates (1997) estimated daily distribution, stability of direct and wandering ambulation cycles, and whether wandering occurring in a two-hour epoch is representative of that occurring in a 24-hour day. A correlational design incorporating direct observation and repeated measures over selected time periods was employed. Twenty-five ambulatory, cognitively-impaired residents from two long-term care settings served as the nonprobability sample.

Measurement of wandering was refined using Martino-Saltzman et al.'s (1991) typology to code the locomoting phase of each independent ambulation cycle. Accordingly, "inefficient" patterns (random, lapping, and pacing) were considered wandering, while "efficient" travel episodes (direct pattern) were not. Further, stopwatch methods were replaced with a portable terminal programmed to time entries, prompt coders, and store and transmit data for analysis. One subject per day was observed 1:1 over an initial 24-hour period beginning at 0700. On the third day following observation the subject was observed again for two two-hour periods: one standard (1400–1600) for all subjects, based on outcome of the study presented above, and a second unique period based on each subject's own 24-hour distributions of hourly ambulation cycle frequency and locomoting phase sums.

Distinct from previous studies, where researchers had classified subjects as wanderers or nonwanderers, this study revealed that all cognitively-impaired ambulatory subjects displayed wandering behavior as operationalized in this study. Although three subjects did not wander at all during the 24-hour period, they did wander during subsequent observation periods. All subjects, regardless of level of cognitive impairment, also displayed direct (nonwandering) ambulation. Descriptive statistics for wandering and direct cycle parameters are summarized in Table 1. Random was the dominant wandering pattern across all subjects, accounting for 77.2% of all wandering cycles, with lapping and pacing constituting 13.2% and 9.6%, respectively. Examination of the hourly frequency distributions of all ambulating revealed that the two-hour period of highest activity, 1700–1900 hours, was also the two-hour period in which the total wandering cycle frequency was greatest at 62 cycles per hour for the group as a whole.

To examine stability of wandering over a three-day period, wandering and direct cycle variables were compared at standard and individual periods. Wandering cycle frequency and locomoting phase sums were moderately and similarly correlated at both individual and standard periods; no direct cycle variable had a significant correlation at either period. For the standard period, all variables were stable for wandering and direct cycles. However, in the individual period, only the locomoting phase sum for wandering cycles was stable and there were more significant differences and, thus, less stability, among direct cycle variables.

The universal expression of wandering among all cognitively-impaired, ambulatory subjects has only been demonstrated in this one sample. Although subjects were drawn from two settings, the sample was small and nonrandom. Thus, further research is needed to validate and generalize this finding. However, it suggests that wandering may be a marker for disease progression or staging and could possibly serve as a measure for the efficacy of dementia treatment strategies in the future.

Table 1 Descriptive statistics for wandering and direct cycle variables over 24 hours ($N = 25$).

	Cycle frequency			*Sum locomoting phase*			*Mean % cycle locomoting*		
	Mean	*Range*	*SD*	*Mean*	*Range*	*SD*	*Mean*	*Range*	*SD*
Wandering	19.7	120	27.3	42.9	199.1	53.2	36.1	88	22.8
Random	15.2	104	23.2	34.6	173.1	46.4	40.1	88	26.2

Direct	22.0	64	13.2	29.0	92.3	18.8	28.9	34.9	10.2

7.17.3 EPIDEMIOLOGICAL DATA

7.17.3.1 Prevalence

Several estimates of wandering prevalence have been published, but all are flawed by unclear and inconsistent criteria for wandering and by mostly nonrandom, small, and incomparable samples. The basis for dementia may also vary by sample, a few being limited solely to subjects meeting diagnostic criteria for Alzheimer's disease (AD). Estimates are also likely influenced by other unknown or uncontrolled factors such as physical restraints and medications.

Among institutionalized demented elderly, estimates of the number of wanderers range from 6 to 24% (Dawson & Reid, 1987; Hiatt, 1980; National Center for Health Statistics, 1979; Wilkinson & Graham-White, 1980). In a random sample of eight nursing homes (Algase, 1988), wherein 747 residents (84% of those eligible) consented to cognitive screening, 5% were classified as wanderers by the nursing staff. As a percentage of those with cognitive impairments, the estimate doubled to 10%. Further, as a proportion of residents who were both cognitively impaired and ambulatory, the ratio was 1:4. Although not intended as an estimate of prevalence *per se,* Algase, Beattie, Kupferschmid, and Beel-Bates (1997) later found that in two long-term care settings, all ambulatory, cognitively-impaired residents, who had not necessarily been labeled as wanderers, displayed the behavior when directly observed over an extended time period. They concluded that if a person's overall ambulation activity was low or the proportion of their ambulation that was wandering was small, nurses tended to *underidentify* the phenomenon. However, in comparing nurses' ratings to observation, nurses have also *overestimated* the behavior (Milke, 1989). Conflicting conclusions may be due to different operational definitions for wandering in these studies.

In community samples of demented elderly, usually based on caregiver informants, estimates of wandering range between 19 and 56% (Burns, Jacoby, & Levy, 1990; Rabins, Mace, & Lucas, 1982; Teri, Larson, & Reifler, 1988). Among 92 consecutive patients with suspected dementia who received a home visit, approximately 37% were reported to get lost when outside the home and 28% when inside the home. These were most often persons with AD, as compared to vascular dementia, and level of cognitive impairment did not affect prevalence (Ballard, Mohan, Bannister, Handy, & Patel, 1991). In a survey of county sheriff's departments, sheriffs were called to locate one missing wanderer per year for every 1000 persons over the age of 65 years (Butler, 1990). Of these, five deaths occurred in 450 incidents. The cost to search for a missing wanderer was US$1200 per incident in law officer time alone. These estimates are conservative, as local police and volunteer fire departments are often the first line of assistance in such searches and therefore a number of events were likely excluded from this survey.

7.17.3.2 Incidence

No estimates for the incidence of wandering, either for the dementias in general or for any single type of dementia, were located. However, in staging dementia, "getting lost" is a criterion for stages 3 and 4 of the Global Cognitive Deterioration Scale (Reisberg, Ferris, deLeon, & Crook, 1982). By these instruments, at least one definition of wandering is accepted as an inevitable part of dementia, to be expected in every instance of the disease. However, the empirical basis for viewing this behavior as representative of a stage of dementia within these systems is unspecified.

7.17.4 PUTATIVE RISK FACTORS FOR WANDERING

7.17.4.1 Personal Factors

Currently, among those with cognitive impairments, knowledge is insufficient to predict who might wander or to specify the nature of the wandering behavior that one is likely to display. Although newer work has cast doubt on whether wandering is confined to a subgroup of cognitively-impaired ambulatory persons (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997), older studies which compare wanderers and other nursing home residents may begin to illuminate the profile of a "problematic" wanderer. Since most of these older studies used nurses' or caregivers' judgments to identify wanderers, they likely represent comparisons between those with the most obvious display of the behavior and those with a low level or more subtle form of wandering. Variables most often reported include demographics, cognitive deficits, mobility, and psychosocial characteristics. Data from 12 samples are summarized in Table 2.

Most of these samples were not randomly chosen and, when comparisons were made with nonwandering controls, controls were generally also cognitively impaired. Wandering was noted in a wide age range of demented persons who were not consistently older or younger than controls. As might be expected, except for the two studies conducted on subjects from the Veterans' Administration, samples were largely female, representing a ratio of approximately 3:1. This gender ratio was maintained among wanderers. Samples were primarily ambulatory, with a few subjects in wheelchairs. When mobility was a variable of interest, wanderers with freedom to walk had better overall mobility than controls. Although wanderers were found among persons with all levels of cognitive impairment, as a group, their performance on global measures of impairment were generally worse than controls. On discrete cognitive tasks, poorer performance was found in memory and recall, abstraction, orientation, and visuospatial skills. Wanderers also had poorer language skills and were less able to communicate even though their personalities were generally more agreeable and extroverted. While none of these studies were strictly aimed at identifying risk factors, their overall results reveal that advanced cognitive impairment, good mobility, and impaired ability to communicate, particularly among individuals with a history of sociability, may portend a tendency to wander.

While the question of whether medical diagnosis, as a basis for dementia, might help to identify wanderers is an interesting one, few studies cast light on this possibility. Several studies do report various types of dementia among wanderers with a range of pathologies including AD, multi-infarct dementia (MID), and mixed dementia (Algase, 1992a; Hope et al., 1994; Thomas, 1997). However, due largely to small sample sizes and the limited nature of medical documentation in long-term care settings (from which most subjects are drawn), little analysis of the relationship between medical diagnosis and wandering has been done. In a random sample of 163 cognitively-impaired nursing home residents, 10% of one sample ($n = 163$) had only an irreversible basis for their dementia, 31% had only a reversible basis, and 59% had a mixed basis (both reversible and irreversible etiologies) noted in their medical records (Algase, 1992a). Wanderers tended to have their dementia due to mixed or irreversible causes. In a sample of 68 nursing home residents, drawn from a 911-bed nursing facility, wanderers ($n = 31$) tended to have a diagnosis of AD while nonwanderers were more likely to have a vascular dementia (Thomas, 1997). However, studies to examine the relative frequency, overall output, and type of wandering associated with various medical bases of dementia have yet to be conducted.

7.17.4.2 Potential Environmental Contributors

Although behavior in general (Lewin, 1935; Murray, 1938), among the aged (Whedon & Shedd, 1989), and within wanderers (Algase, 1992b; Algase & Struble, 1992; Hussian, 1981), is understood to arise as a function of person–environment interaction, few studies have yet explicated physical or social factors in the environment that may precipitate or otherwise influence wandering.

In a case study, observation of the intrusions of one wanderer into the rooms of other residents revealed a consistent pattern: attraction to a limited number of rooms which shared a common view of the outdoors and dalliance at a particular dresser with a mirror (Donat, 1984). By reassigning the wanderer to the room most frequently entered and containing the dresser, intrusions into other rooms decreased from an average of 16 per hour to less than two. While manipulating the environment had an effective outcome for those intruded upon, it made no real change in, but rather accommodated to, the subject's behavior. Thus, both the theoretical and practical value of this study is limited as no attempt to analyze attracting environmental features from a conceptual standpoint was made.

In analyses of the nursing home environment for its impact on agitated behaviors, observations of pacing (including "aimless" wandering) under naturally occurring conditions were also reported (Cohen-Mansfield & Werner, 1985; Cohen-Mansfield, Werner, & Marx, 1989;

Table 2 Characteristics of 12 samples of wanderers.

Cohen-Mansfield, Werner, Marx, & Freedman, 1991). Features of the physical environment in which wandering increased included location (corridor, nurses' station, and another resident's room) and normal lighting, noise, and temperature conditions. With colder temperatures, wandering decreased. Wandering also decreased significantly under certain social conditions, namely during structured activities and activities at daily living (ADLs), but increased in the presence of a few people (2–5) or when housekeeping staff or residents from another unit were present. However, these researchers made no attempt to manipulate environmental factors to elucidate effects on wandering.

Work on wandering in controlled environments wherein aspects of the environment are specifically manipulated is just beginning. To test the premise that the low light conditions associated with sundown increase confusion and wandering, a study of 10 wanderers was conducted in a specially controlled nursing home lounge. Preliminary analysis revealed no impact of various lighting conditions (dim, bright, or average ambient lighting) on the frequency of wandering episodes or total time wandering in the lounge (Algase, 1997a). However, although subjects were observed during the time of day when each was normally most active, they displayed very little wandering in the highly simplified, controlled environment of this study, suggesting that other aspects of the environment may have a greater potential to reduce wandering than light.

7.17.5 PUTATIVE OUTCOMES OF WANDERING

Outcomes of wandering have not been extensively studied and most knowledge concerning them has been derived from clinical experience. Falls and elopements are the direct, more immediate, and, due to their association with high morbidity (e.g., hip fractures) and mortality, the most serious outcomes of wandering. Weight loss, sleep disturbances, and fatigue are more indirect outcomes thought to reflect wandering's cumulative effects (Algase & Struble, 1992). An outcome that is not well documented, but frequently observed in the course of my clinical practice and research, is the tendency of other nursing home residents to shun or berate wanderers, most likely in an effort to protect themselves, their space, and their possessions from unwelcomed intrusions. Although effects of such negative responses to wandering on morale of wanderers is unknown, logic suggests that it is not a pleasant experience. In fact, it is not uncommon for such interactions to be verbally hostile, and they can escalate into physical aggression on the part of either party.

7.17.5.1 Falls

While cognitive impairment is the most important and frequently documented risk factor for falls (Buchner & Larson, 1987; Janken, Reynolds, & Swiech, 1986; Morse, Tylko, & Dixon, 1987; Nevitt, Cummins, Kidd, & Black, 1989; Reinboth & Gleidenvand, 1982; Rubenstein, Josephson, & Robbins, 1994; Tinetti, Speechley, & Ginter, 1988; Walshe & Rosen, 1979), little empirical data exists to support the clinical contention that wandering compounds the risk of falling (Cancro, 1968; Soverini & Borghesi, 1968). However, any such effects are probably mediated by disturbances in gait and balance associated with cognitive impairment itself (Kippenbrock & Soja, 1993; Morse, Tylko, & Dixon 1985; Morse et al., 1987). Characteristics of wanderers or types of wandering most likely to result in falls are unknown.

The higher frequency of and time spent in ambulation among wanderers may simply increase opportunity to fall. Wanderers as a whole are thought to be more physically able than less active persons with cognitive impairments. However, as dementia progresses, wandering increases at the same time as physical vigor declines for a given individual. Thus, the ability to apprehend and interpret environmental hazards worsens in tandem with deterioration in one's physical stamina. Based on a study of 60 institutionalized women with AD, researcher's concluded that falls were related to a decline in overall vigor in those who had been active (Brody, Kleban, Moss, & Kleban, 1984). Together, these factors may interact to increase the incidence of falls among wanderers.

7.17.5.2 Elopements

The most potentially dangerous consequence of wandering is elopement (Henderson, 1993–4; Mulrooney, 1993–4). Elopement, the unattended leaving of the premises, has been linked to out-of-facility deaths (Foxwell, 1993; Morino, 1989). While reported elopements have declined, largely due to growth of dementia units equipped with sophisticated security systems, they remain a serious and costly problem (Henderson, 1993–4). Death or serious injury occurring during elopement accounts for an estimated 17% of malpractice suits directed toward long-term care facilities (Kapp, 1986).

Risk management programs and in-service education, while essential in training personnel, have not demonstrated a reduction in the incidence of elopement (Kapp, 1986). Due to nursing home reforms contained in the Omnibus Budget Reconciliation Act (OBRA), the use of restraints to ensure safety for persons who wander is increasingly challenged, legally and empirically, because of known undesirable side effects of restraint use (Evans & Strumpf, 1989; Miller, 1975). Thus, the need for alternative approaches to reduce or control elopements, based upon a clearer understanding of particular wandering behaviors and circumstances precipitating egress, remains.

7.17.5.3 Weight Loss

Weight loss is associated with progressive dementia. In one study of hospitalized patients who were no longer mobile, those with AD were an average 11.3 kg (21%) lighter than those who were not demented and 6.6 kg lighter than those with MID despite comparable nutritional indices and food intake for all three groups (Singh, Mulley, & Lusowsky, 1988). In a retrospective comparison of weights recorded in the medical records of these same patients, body weight fell significantly for those with AD but did not change appreciably for the others. Reasons for these differences are poorly understood.

No studies examining the effects of wandering on weight, food intake, or nutritional indices were located. However, whatever the basis for weight loss in dementia and particularly in AD, wanderers may be prone to even greater losses for two reasons. First, their activity level and, therefore, their energy expenditure is high. Second, due to their activity level, wanderers are often difficult to keep seated and focused during mealtimes. Although they are usually capable of feeding themselves, wanderers often walk away from the table before having consumed their entire meal and, thus, may be at greater risk for insufficient caloric intake to offset their high level of energy expenditure.

7.17.5.4 Sleep Disturbance and Fatigue

Sleep patterns in dementia are altered to a degree even greater than that attributable to aging (Prinz, Peskind et al., 1982). The sleep of persons with dementia is punctuated with frequent arousals and nearly devoid of the deep sleep and REM sleep needed for physical and mental restoration (Vitiello, Poceta, & Prinz, 1991). Brief daytime naps are also common.

While the effects of wandering on sleep have not been reported, an examination of the individual 24 hour distributions of wandering episodes in 58 nursing home residents with cognitive impairment does confirm that wandering occurs during the night (Algase, 1997b). However, by comparison to daytime wandering, the frequency of night-time episodes and their total duration is quite small (see Figures 1 and 2). Distributions vary widely among subjects and not all daytime wanderers display the behavior at night. In an analysis of six cases, three with severe levels of cognitive impairment displayed wandering behavior during more hours in a day (9–19) than three with moderate levels of impairment (6–8). The longest period of time without a wandering episode was shorter for those with severe impairment (5–10 hours) than it was for those whose impairment was moderate (14–16 hours) (Algase, Beel-Bates, & Kupferschmid, 1995). Thus, wanderers, particularly those with more advanced cognitive loss, receive little uninterrupted rest.

What is unknown is whether the propensity to wander interferes with sleep to a greater degree than dementia itself or whether the fractured sleep patterns accompanying dementia inadvertently provide greater opportunity to wander. Clearly, more studies are needed to explicate relationships among sleep, fatigue, and wandering, as rest periods may be a potentially useful intervention (Hall & Buckwalter, 1987).

7.17.5.5 Other Possible Outcomes

Longitudinal effects of unrestrained wandering have been the focus of only one study (Cornbleth, 1977). Physical, psychosocial, and cognitive outcomes were assessed in a sample of 48 veterans prior to and at 6 and 12 weeks following their transfers between an experimental and other wards. Controlling for baseline performance, wanderers *on* the experimental ward, where they were free to walk about at will, showed greater physical ability (range of motion) at both postmove time points as did nonwanderers *off* the experimental ward. However, regardless of ward assignment, wanderers showed lower psychosocial functioning over time, reflected primarily in terms of friendliness, self-control, and communication skill than nonwanderers. Neither ward nor group had an effect on measures of cognitive performance.

Thus, not all outcomes of wandering are negative. Although no measures of wandering behavior were employed to demonstrate an actual increase in ambulation on the experimental ward, the above study reveals that

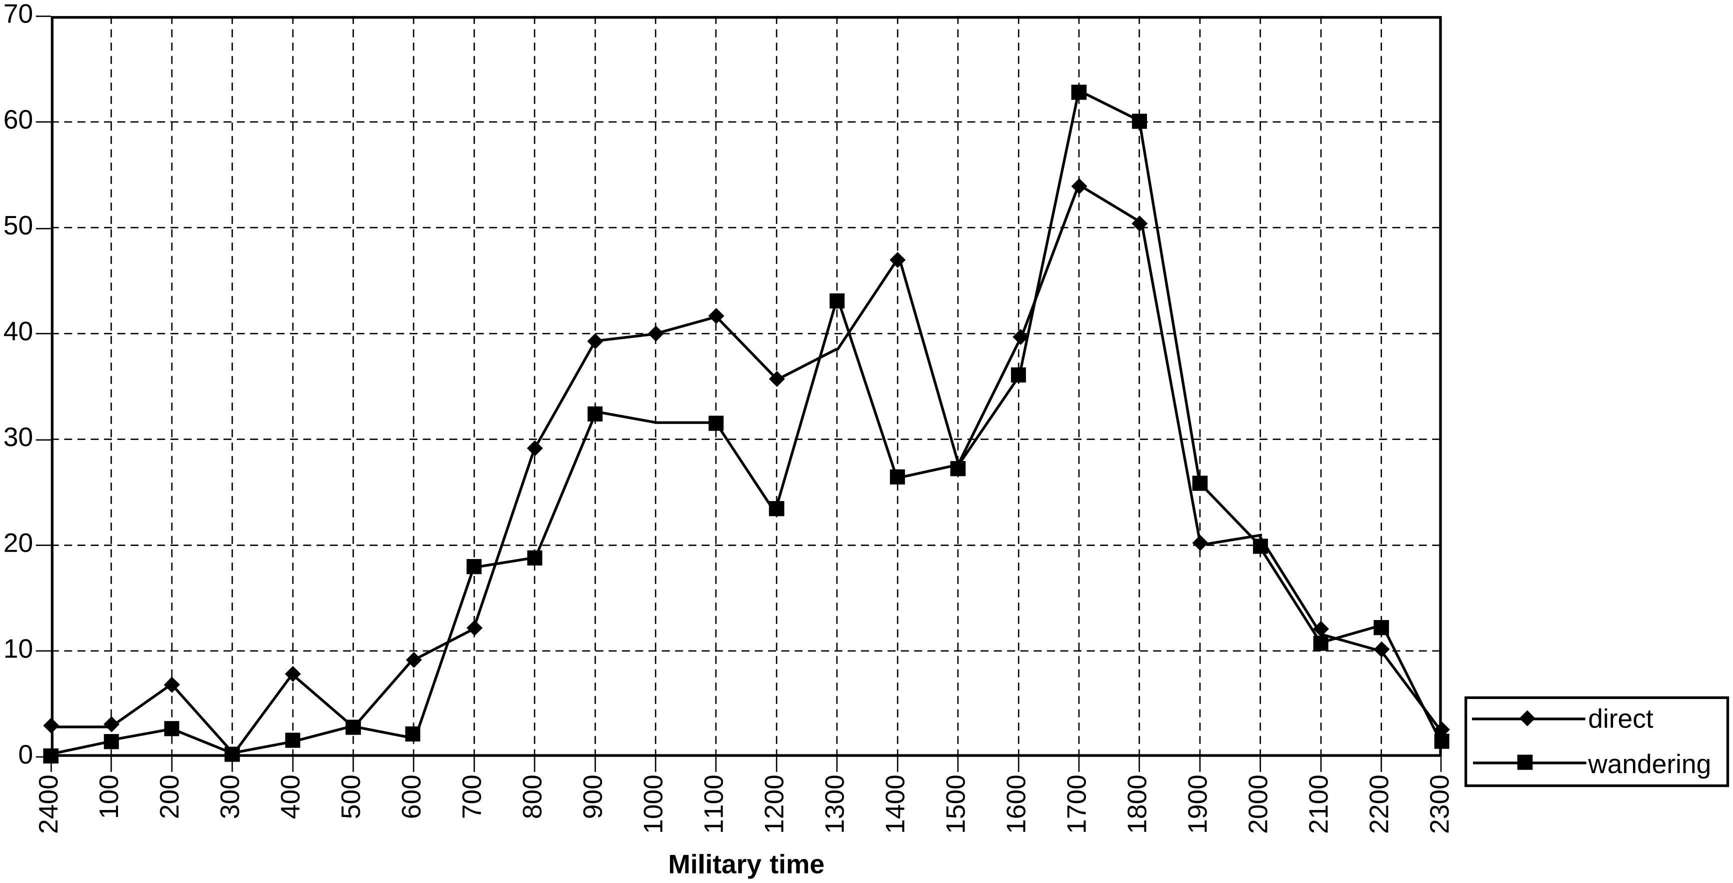

Figure 1 Sum of wandering and direct episode frequencies by hour (N = 25).

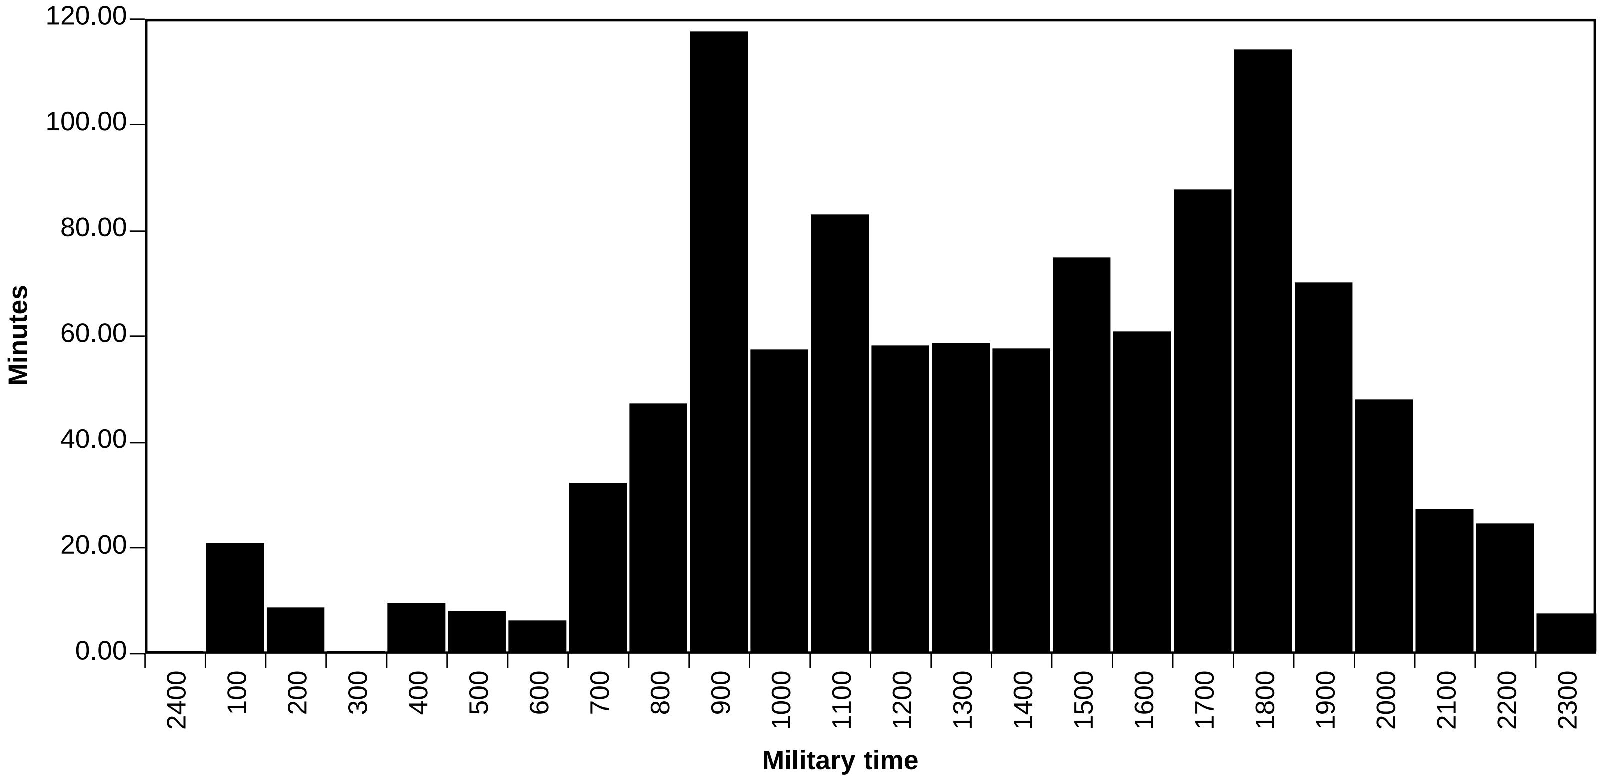

Figure 2 24-hour distribution of minutes spent wandering ($N = 25$).

physical functioning may be enhanced by freedom to wander. Unfortunately, on wards housing both wanderers and nonwanderers, such freedom for wanderers may adversely affect nonwanderers, who may inhibit their movements as a protective strategy. Further, wandering may have a negative impact on the psychosocial skills of those afflicted.

7.17.6 ETIOLOGIC THEORIES AND FACTORS

While several etiologies for wandering have been suggested, none as yet fully explain it. Most explanations are speculative, lacking adequate testing, yet all remain viable as hypotheses. The most glaring deficiency in efforts to test these "theories" is a reliance on proxy variables for wandering, rather than on any direct, valid, and reliable measure of the behavior itself. When eventually tied to observable features of wandering, each of these various theories may be able to explain some dimension or type of the behavior, thereby lending direction to more targeted intervention strategies for the most troubling aspects of wandering.

7.17.6.1 Wandering as Spatial Disorientation

Based on multiple findings from lesion and other studies on rats, the hippocampus (HPC), situated deep in the parietal lobe, is known to capture memories of spatial environments (Nadel, 1991). In humans, the right HPC has a special role in spatial learning (Goldsten, Canavan, & Polkey, 1989) and HPC damage is a classic neuroanatomical feature of dementia, particularly in AD. Further evidence supporting specific involvement of the right parietal lobe in wandering is drawn from a recent study of 18 subjects with vascular dementia, nine of whom were identified as wanderers on the basis of behaviors observed by staff in a long-term care setting (Meguro et al., 1996). Using positron emission tomography (PET), these researchers demonstrated that wanderers had significantly higher cerebral metabolic rate for glucose (CMR_{glc}) than nonwanderers in the left and right frontal lobe, left parietal lobe, temporo-parieto-occipital region, left occipital lobe, and cerebellum. Thus, while the CMR_{glc} of the right parietal lobe of wanderers was neither higher nor lower than nonwanderers, it was relatively lower than other brain regions for wanderers.

Impaired spatial memory is an expected feature of dementia and "getting lost" in familiar or unfamiliar surroundings has been used to characterize particular stages of cognitive decline (Reisberg et al., 1982). Several researchers have demonstrated the presence and nature of spatial disorientation in AD and other dementias. In tests of parietal lobe function, wanderers ($n = 5$) were shown to perform more poorly than similarly demented controls ($n = 16$) (deLeon, Potegal, & Gurland, 1984). Using neuropsychological measures of visuoconstructive (right parietal) performance, long-term declarative memory, attention, language performance, and dementia severity, Henderson, Mack, and Williams (1989) examined spatial disorientation, evaluated by caregiver ratings on four items (wandering, getting lost indoors, getting lost on familiar streets, unable to recognize familiar surroundings) from the Memory and Behavior Checklist (S. Zarit, Orr, & J. Zarit, 1985) in a sample of 28 ambulatory persons who met criteria for probable AD. Eleven subjects (39%) showed substantial spatial disorientation yet did not differ from remaining subjects by age, education, duration of symptoms, or gender. Correlations of neuropsychological measures to spatial disorientation ranged from 0.21 (attention) to 0.56 (long-term memory). Long-term memory and visuoconstructive performance together explained 41% of the variance in spatial disorientation with memory being the stronger predictor.

Visuospatial ability has also been examined in relation to right–left orientation (R/L-O) in AD and MID subjects with comparable dementia severity. Operationalized by putting geometric objects through holes of corresponding shape, visuospatial ability was significantly correlated to R/L-O (as applied both to self and external to self) in MID with focal lesions, but not in AD (Fischer, Marterer, & Danielczyk, 1990). In a study comparing AD and Parkinsons' dementia (PD), both groups, which were matched for dementia severity, age, and education, performed substantially worse on visuospatial tests than nondemented controls (Mohr, Litvan, Williams, Fedio, & Chase, 1990). Further, these PD subjects showed a selective deficit on the Object Assembly subscale of the WAIS-R, a task not principally associated with memory and thought to depend on frontal lobe functioning. However, the AD subjects performed more poorly on tasks with principal memory components, likely reflecting involvement of the HPC which, while always affected in AD, is not consistently so in PD (Chiu et al., 1986; Jellinger, 1987).

Still unknown from these works is the correspondence between these measures of visuospatial ability, which are done in grasping space, and performance of spatial tasks, such as way-finding, which occur in large-scale space. A study by Liu, L. Gauthier, and S. Gauthier (1991) lends support to linkages in performance at these two spatial levels. These researchers administered an array of tasks reflecting perceptual, cognitive, and functional spatial skills to 30 subjects, 15 with early AD and 15 age-matched normals. Perceptual spatial skills included figure-ground perception, visual and tactile shape recognition, visual and tactile size discrimination, position in space, spatial relations, and left–right orientation. Cognitive spatial skills were: spatial planning, decision-making, problem-solving, mental direction rotation, immediate spatial memory, spatial learning, and mental representation of both a familiar and a new environment. While all skills in the perceptual category and most in the cognitive category were performed within grasping space, one (problem solving) in the latter group did require walking in a large-scale space that afforded total visual accessibility. Orientation within a familiar and a new environment were the functional spatial skills examined. Both of these required walking to specified locations that were not immediately visible from one's point of origin.

Some perceptual skills were intact for AD subjects, namely visual shape discrimination, both visual and tactile size discrimination, and left–right discrimination. However, the measure of left–right discrimination favored application to self, as opposed to application external to self. AD subjects displayed gross disturbance of cognitive skills, performing significantly worse than normal controls on all tasks in this category. In finding their way about a highly familiar environment, AD subjects did as well as controls, but in a new setting they performed only half as well as controls.

While results of these studies indicate that spatial orientation is disturbed in dementia, the relationship of performance on various visuospatial tasks to observed travel patterns and ambulation efficiency and to the frequency, duration, distribution, and location of wandering remains unknown. Effective and efficient ambulation depends on spatial memories, also known as cognitive maps. In fact, building spatial memories requires some degree of exploration, which includes ambulation. As a kind of ambulation occurring concomitant with AD and other dementias, it seems reasonable to postulate that at least some aspects of wandering, most likely its geographic or spatial patterns, may reflect deterioration of such maps (i.e., difficulty remembering one's way around), or reduced capacity to form new maps (i.e., difficulty learning one's way around). Evidence for the link between spatial disorientation and the spatial patterns of wandering is found in the swim patterns of rats. Rats with unilateral and bilateral HPC damage swim in patterns resembling, respectively, the lapping and random travel patterns of demented elderly observed by Martino-Saltzman et al. (1991) (Holden & Therrien, 1993).

7.17.6.2 Wandering as a Movement Disorder

7.17.6.2.1 The HPC and locomotor output

Three presently unrelated views have been offered to explain the high level of movement in wanderers. The first again involves the HPC. In addition to its role in spatial orientation, researchers have demonstrated that the HPC also affects the amount of locomotion. Classical work (Ranck, 1973; Vanderwolf, 1969; Vanderwolf, Kramis, Gillespie, & Bland, 1975) first established that the electrical activity of cells in the HPC is correlated with locomotion. Work in 1994 by Whishaw, Cassel, Majchrzak, Cassel, and Will suggests that animals with damage to HPC shift towards more locomotion (i.e., shorter stop periods) on what is termed the mobility gradient. Specifically, theta units (groups of neurons, most likely HPC interneurons and/or dentate granule cells) produce a characteristic theta rhythm (7–10 Hz; also known as rhythmic slow wave activity). Rhythmical firing of theta units occurs when animals are walking, running, jumping, or moving the head. In contrast, predominantly irregular wave patterns and low rates of irregular firing or absence of theta is seen during motionless periods or with appetitive behaviors like grooming, chewing, etc. (Vanderwolf & Leung, 1983; Whishaw, 1991), suggesting that theta activity is involved in generating rhythmical locomotion and modulating movements and that intrinsic pacers of this rhythm basic to locomotion exist (Morgenson & Nielsen, 1984; Muller & Kubie, 1989; Traub, Miles, & Wong, 1989; Whishaw & Nikkel, 1975).

In humans, case reports of HPC theta exist from EEG recordings, although theta is difficult to record without invasive procedures and special electrode placements. However, Halgren (1991) has recorded action potentials related to movements requiring intention or high effort, indicating that human HPC neural activity strongly influences movement. Further he suggests (Halgren et al., 1980) that these are endogenous potentials or pacers. Thus, the well-established involvement of the HPC in AD and some other dementias may also explain the overall increase in locomotion observed among wanderers.

7.17.6.2.2 Perseveration

Perseveration, or difficulty in stopping or shifting behavior, is a second possible characterization for the overall high activity levels of wanderers. In other words, once walking is initiated, wanderers may have difficulty terminating an episode. Present with focal damage to the parietal and temporal lobes (Goldberg, 1986; Sandson & Albert, 1984) and with more diffuse central nervous system pathology (Goldberg, 1986), perseveration manifests as repetitive behavior, usually without a discernible stimulus. Perseveration is a documented feature in many cases of AD, MID, and PD (Fuld, Katzman, Davies, & Terry, 1982; Marley, 1982) and can involve repetitious speech patterns (e.g., echolalia, word intrusions) and motor behaviors.

This possible view of wandering was the basis of a study by Ryan et al. (1995). Eighteen community-residing subjects (72% female) with mild to moderate dementia were classified as wanderers ($n = 6$) or nonwanderers on the basis of caregiver ratings. Three types of perseverative motor behavior were quantified from subjects' drawings on the Bender Gestalt and clock drawing tests. The groups did not differ with regard to attention and concentration, spatial orientation, age, gender, or dementia severity. Wanderers demonstrated significantly greater perseveration than nonwanderers, although nonwanderers did perseverate. Wanderers were especially likely to have an ongoing, continuous, or repeated response to a singular stimulus, a form of perseveration associated with the right hemisphere and with attention or motor output deficits (Marley, 1982) or to carry over elements of one drawing into another, a form of perseveration associated with bilateral frontal or frontotemporal impairments (Sandson & Albert, 1987). Interestingly, authors of this study did not confirm spatial orientation deficits of wanderers reported above. They attributed this lack of difference to either their method for scoring the clock drawing test or to the earlier stage of dementia of their subjects.

7.17.6.2.3 Effect of neurotransmitters

A third hypothesis addressing the high degree of motor output of wanderers is not based on localization to particular brain structures or regions, but involves neurotransmitter systems. Weller (1987) suggested that the reduction of acetylcholine characteristic of AD may result in a relative excess of dopamine. Seeing wandering as indicative of restlessness, he further proposed that, analogous to its role in schizophrenia, this dopamine "excess" may account for wandering. However, no studies to evaluate this hypothesis could be located.

7.17.6.3 Wandering as a Circadian Rhythm Disruption

The suprachiasmatic nucleus (SCN) is thought the be the "biological clock" that governs daily fluctuations occurring in, at least, some physiological and behavioral phenomena in humans. Because the SCN is located atop and connected to major optic tracks in the brain, phenomena that naturally change in accord with the light–dark cycle, such as activity and rest, are more likely affected by it. The SCN decreases in size with aging and, to an even greater extent, in AD (Swaab, Fliers, & Partiman, 1985). Loss of neurons in the SCN accounts to a large degree for degradation in the normal sleep–wake cycle observed in both aging and AD (Prinz, Peskind et al., 1982; Prinz, Vitaliano et al., 1982; Witting, Kwa, Eikelenboom, Mirmiran, & Swaab, 1990). Further, if neuronal loss causes the SCN to fall below a certain critical mass, circadian periodicity may be completely obliterated (Brock, 1991).

Along with wandering, day–night reversal and "sundowning" are other clinical concerns observed in dementia that may coincide with shrinkage of the SCN. In fact, several authors have actually linked sundowning with wandering (Eisdorfer & Faan, 1982; Rindlisbacher & Hopkins, 1991). One group (Rindlisbacher & Hopkins, 1992; Rindlisbacher, Hopkins, & Grant, 1992) studying sundowning has used methodology (activity monitoring) similar to that used by researchers studying wandering (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997; Satlin et al. 1991).

As sleep and physical activity are mutually exclusive, an inverse relationship between sleep and wandering would be expected. Thus, changes in overall circadian periodicity associated with AD and other dementias are likely to affect the daily distribution of wandering episodes. Figure 3 illustrates this likelihood as the data depicted for severely impaired cases, where SCN shrinkage would be advanced, show more night-time wandering and wandering occurring in more hours of the day than the data shown for moderately impaired cases. Further evidence supporting the role of the SCN in affecting wandering distribution is found in a comparison of AD subjects classified as "pacers" and "nonpacers" (Satlin et al., 1991). These researchers reported that relative amplitude in 24 hour activity patterns was lower for pacers, suggesting a weakening and loss of integrity in circadian periodicity that exceeds that of nonpacing AD victims.

7.17.6.4 Wandering as an Expression of Mood or Affect

Terming it "agenda behavior," clinicians have attributed wandering to affective states, such as anxiety or fear, underlying the here-and-now experience of a cognitively impaired person (Rader et al., 1985). However, while an appealing explanation because of its potential for intervention, little research yet exists to substantiate this claim. While Cohen-Mansfield and Marx (1990) demonstrated a connection between depression and screaming behaviors, no such relationship between depression and wandering was revealed. In a more recent work wherein agitation was viewed as a reflection of negative affective states such as anxiety or anger, researchers (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997) used Cohen-Mansfield's Agitation Inventory (CMAI) to explain rhythmic parameters for various patterns of wandering. The physical aggression subscale (PA) of the CMAI, which contains behaviors suggestive of anger or frustration, accounted for 37% of the variance in cycle frequency and 43% of the variance in the sum of locomoting phases for all wandering patterns together (random, lapping, pacing) over a 24 hour day, with most of this attributable to the predominance of random-pattern wandering. The PA factor also accounted for 40% of the variance in the mean locomoting phase duration and 54% of the variance in the percentage of a cycle spent in locomotion for the pacing pattern. The physically nonaggressive subscale (PNA), which contains behaviors suggestive of anxiety or restlessness, accounted for 18% of the variance in cycle frequency, 19% of the variance in the 24-hour locomoting phase sum, 23% of the variance in the nonlocomoting phase mean, and 30% of the variance in the percentage of cycle locomoting for all wandering patterns together. Again, cycle frequency and locomoting phase sum results are largely attributable to the preponderance of random-pattern wandering displayed by subjects. However, nonlocomoting phase mean results were most influenced by lapping, for which the PNA predicted 39% of the variance. Results for the percentage of cycle spent in locomotion were largely influenced by pacing, for which the PNA predicted 61% of the variance. The verbal aggression subscale (VA), which contains behaviors suggestive of anger and general confusion, predicted only the nonlocomoting phase mean (19%) for random-pattern wandering. While promising, results should be viewed with caution as no controls for the effects of cognitive impairment were considered in these analyses. Although preliminary and based only on a convenience sample of 25 long-term care residents, these results do suggest that affect may be important in the expression of particular parameters of wandering and, with further study, these may be useful in identifying what kind and amount of wandering might be explained by affect and, thus, be potentially influenced by interventions targeted to change affect.

7.17.6.5 An Emerging Multifactorial Explanation for Wandering

A group of investigators devised a putative explanatory model for wandering and other dementia-related behaviors based on an extensive review of the literature (Algase et al., 1996). Potential etiologies were grouped and organized as either background factors (i.e., the relatively stable or slowly changing characteristics of persons with dementia) and proximal factors (i.e., the more fluid and dynamic features of the person or the environment). Background factors included dementia-compromised functions (e.g., memory, circadian rhythms), health state, demographics, and psychosocial variables (e.g., personality, response to stress); proximal factors included physiological need states (e.g., pain, hunger), psychological need states (e.g., affect), physical environment (e.g., light level), and social environment (e.g., staff stability). In addition to factors thought operative for any dementia-related behavior, a particular set of additional factors were also delineated for selected behaviors, including wandering. Additional variables posed as relevant to wandering were level of social engagement, complexity of environmental design, and crowding.

Figure 4 is a more recent schematic of the model as it pertains to wandering alone. Major propositions of the model are that: (i) background and proximal variables interact or combine in some way to produce wandering, (ii) proximal variables are perceived in the context of existing background variables, and (iii) some background variables may have a direct influence on wandering independent of any proximal variable. Accordingly, unless it is a direct result of an underlying neuropathology, wandering arises from some immediate perceived need and is expressed in a way that is compromised by dementia and mediated by environmental considerations.

The authors acknowledge that the model is tentative and requires empirical testing. How-

ever, it is noteworthy in that it represents effort to advance a more comprehensive, integrated, and detailed view of this complex behavior. Further, it does so in a way that can lend support to development of specific intervention strategies for particular parameters or aspects of wandering that present problems or issues in particular contexts.

7.17.7 ASSESSMENT TECHNIQUES AND ISSUES

Most studies of wandering are actually studies of wanderers; few focus on the behavior itself and many of those actually target only exit behavior. Yet, research does provide some guidance for the clinical assessment of wandering behavior. Three measurement strategies used by researchers for quantifying wandering could be applied or adapted for the purposes of clinical assessment: mapping techniques, counting and timing strategies, and motion meters. Each is discussed in the sections that follow. In addition, sections addressing the assessment of clinical concerns and potential outcomes from wandering are offered.

7.17.7.1 Assessment Techniques for Wandering

7.17.7.1.1 Behavior mapping

The earliest study in which wandering behavior was quantified employed a behavior mapping strategy (Snyder et al., 1978). For designated time periods, episodes of locomotion were observed and traced on a floor plan of the unit where the wanderer resided. This approach captured approximate distance covered, areas of the unit where locomotion occurred, and number and heading of turns or direction changes. Robb (1987) extended this approach by adding recordings of time spent in each location and observation of several associated motor behaviors. Clinically, such data could be used to estimate relative amount of locomotion; to identify times of day when locomotion is greater or lesser than others; to document changes over time, including comparisons pre- and postintervention; and possibly to provide clues regarding both environmental stimuli that precipitate or repel wandering activity and personal factors that may influence the nature of one's wandering, such as lateral neglect. Supplemented by notes that capture other concurrent events or behaviors, mapping could reveal much about an individual's wandering to assist the selection or development of an individualized treatment program. However, this mapping approach does not differentiate wandering from nonwandering locomotion.

7.17.7.1.2 Counting and timing strategies

Researchers have also attempted to quantify wandering by counting and timing individual walking episodes (Algase & Cheng, 1992a; Algase & Tsai, 1991). Using a rhythm perspective, they cast each episode of wandering as a cycle with locomoting and nonlocomoting phases. By timing each phase, various parameters, such as cycle period (locomoting plus nonlocomoting phase) or percentage of cycle locomoting (locomoting phase divided by cycle period) can be calculated. By aggregating observations over specific time periods (e.g., hourly), additional parameters, such as cycle frequency or mean locomoting phase, can also be determined and graphed for a picture of variation over time. In later work, Algase combined her rhythm view with Martino-Saltzman and associates' typology of travel patterns to differentiate wandering from nonwandering locomotion and to compare cycle parameters for different wandering patterns (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997). An example of a 24 hour graph of data resulting from this approach is shown in Figure 5. This strategy has also been combined with the recording of related behaviors, such as activity prior to and at the conclusion of the locomoting phase of each cycle (Algase & Cheng, 1992b).

The counting and timing of locomotion episodes, combined with the use of Martino-Saltzman's patterns and observation of antecedent and consequent activity or events, can provide powerful information, both scientifically and clinically. While researchers have observed continuously over time periods ranging from 2 to 24 hours and recorded data on portable terminals, a useful clinical picture can be obtained using less costly and technologically sophisticated approaches. By limiting observations to ten minutes per hour over a three-day period, a good baseline can still be documented for identifying times of relatively high and low activity and for comparing changes over time or in response to interventions (Algase & Struble, 1992). Low-tech stop watches and paper and pencil recording approaches can replace more sophisticated and costly computerized approaches. An individual's dominant wandering pattern, which may give cues to an underlying etiology, can also be determined. Further, by including observations of antecedents and consequences, assessment data can be used to inform the design of individualized behavior management strategies.

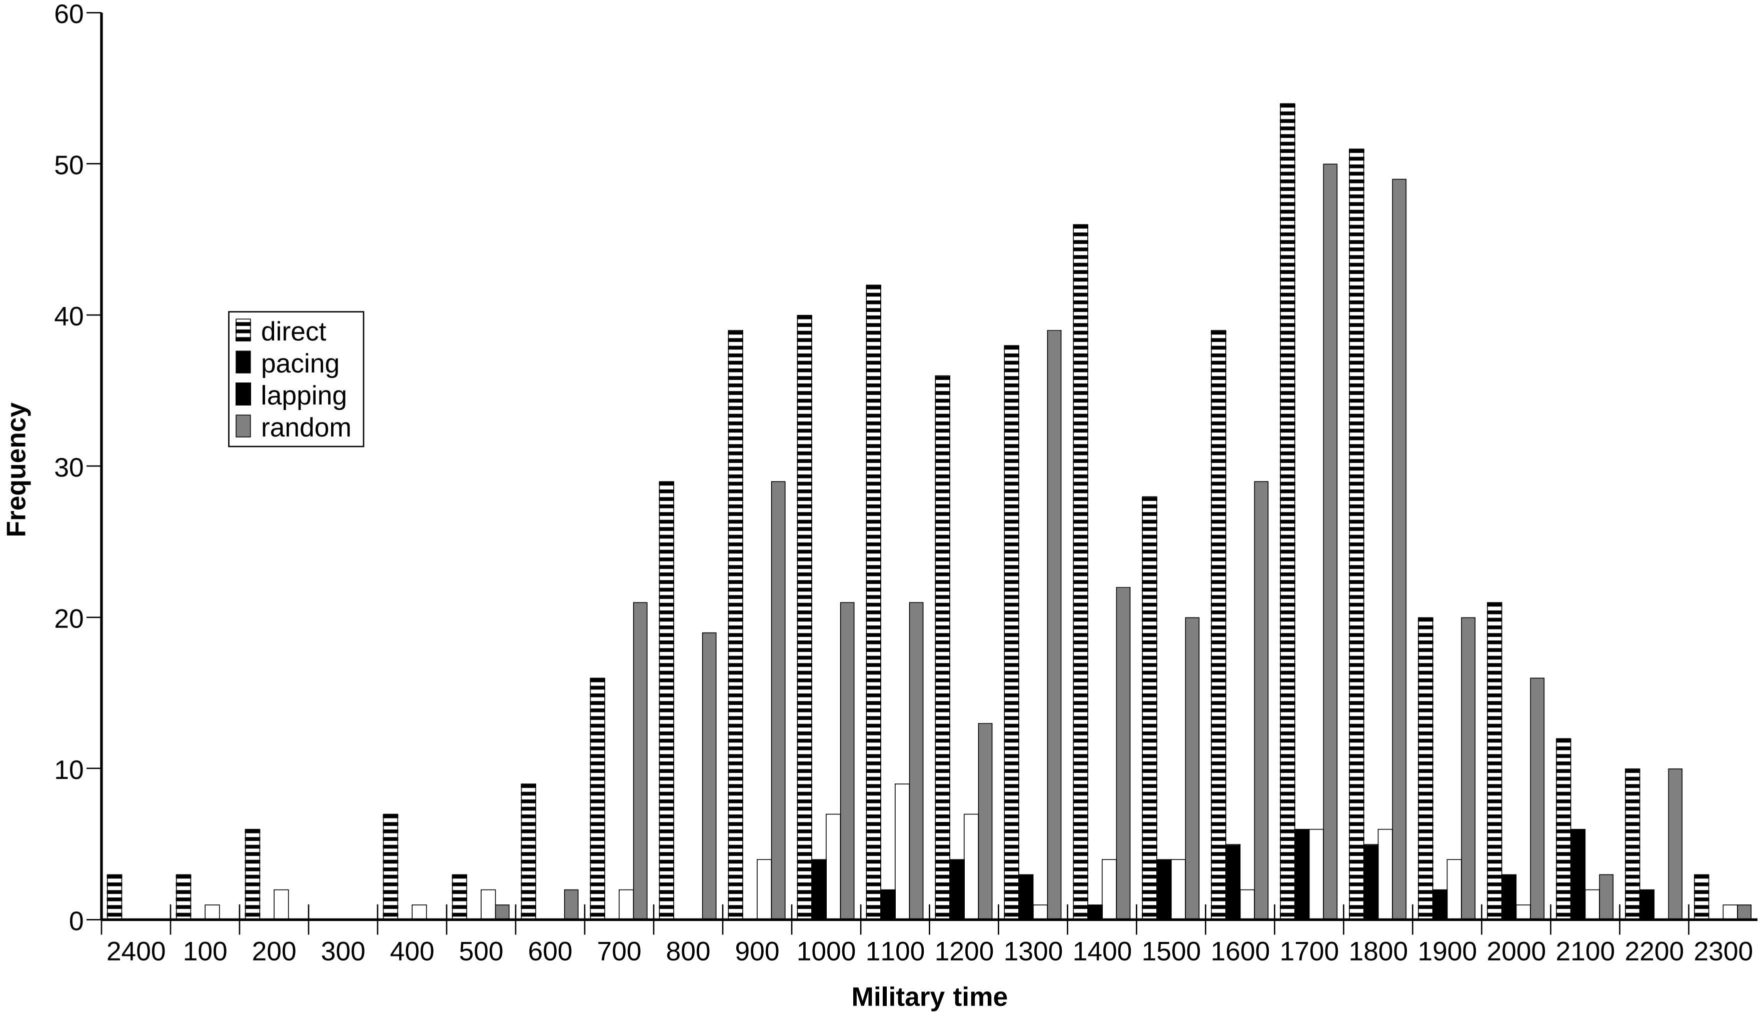

Figure 5 24-hour distribution of wandering episodes by pattern (N = 25).

7.17.7.1.3 Activity monitors

Cognizant of the expense and reliability issues associated with direct observation, researchers are beginning to test biomechanical motion detectors and pressure-sensitive counters for their ability to estimate wandering behavior (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997; Algase & Cheng, 1992a; Madson, 1990). Although only in the preliminary stages of investigation, these devices hold promise for clinical as well as research purposes.

Large-scale integrated (LSI) monitors, watch-sized devices worn on the wrist, waist, or ankle, record changes in position by tripping an internal mercury switch. Movements are aggregated over time and registered in increments of 10 units or 160 movements. LSIs, originally developed for epidemiological research to quantify physical activity in the general population, are effective for aggregating frequency, but not intensity of movement (LaPorte et al., 1979). Because of their sensitivity, LSI monitors are considered well suited to assessing activity associated with skeletal muscle movement in elderly and/or disabled persons (LaPorte et al., 1983). Reliability estimates for LSIs (correlating day-to-total and evening-to-total readings) under laboratory and field conditions across a variety of populations, including postmenopausal women, are stable at values exceeding 0.70 (LaPorte et al., 1982).

In studies of wandering rhythm spanning 24 hours (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997; Algase & Tsai, 1991), LSIs were used reliably; interunit reliability ranged from 0.76 to 0.93. They provided a relatively strong index of wandering over a 24-hour period but their ability to index wandering over a two-hour period was weaker; ankle applications were more valid than waist applications (Algase, Beattie, Kupferschmid, & Beel-Bates, 1997). LSIs were more effective for indexing parameters of wandering cycles alone than for approximating these for direct cycles alone. The use of LSIs as a proxy for direct observation over short time periods cannot be recommended confidently without further study using larger samples. Further, LSIs are not capable of detecting pattern.

Since 1990 new devices have been developed for the measurement of motor output. Examples are the Step-sensor (Madson, 1990) and Actillume (Ambulatory Monitoring Incorporated). Only the Step-sensor was developed specifically to quantify wandering. Composed of a heel pad, worn in the shoe, and a hardware component attached to the outer aspect of the shoe, the Step-sensor was highly reliable for recording actual number of steps taken when tested in a sample of elderly nursing home residents (Madson, 1990). These devices, alone or in combination, may estimate rhythmic aspects of wandering by demented persons more specifically and sensitively than LSI monitors. However, none yet posses the capacity to identify wandering patterns. The reliability, validity, and clinical acceptability of these devices for assessing wandering in a sample of demented elderly is unknown and is currently under investigation by Algase and associates in a nationally funded US study.

7.17.7.2 Assessment for Associated Clinical Concerns

A number of clinical concerns are associated with wandering and these deserve thorough assessment both for their contribution to and impact on this behavior. These are discussed below in relation to necessary foundational abilities, mediating factors, and antecedents and consequences.

7.17.7.2.1 Foundational abilities

Good gait, balance, and sensory capabilities undergird the ability of persons to walk safely. Regardless of deficiencies in these abilities, cognitively-impaired persons are known to move about their environment. Because of cognitive limitations, it is seldom effective to simply remind them to use special caution or assistive devices. Thus, good assessment and attention to these abilities is needed.

In contrast to declining intellectual abilities, systematic studies have established that motor function remains normal until the final stages of AD, the most prevalent dementia (Fayden & Townsend, 1976; Koller, Wilson, Glatt, & Fox, 1984; Molsa, Martilla, & Rinne, 1984). Progressive rigidity and limb flexion eventually lead to loss of balance, impaired ambulation and immobility, but psychomotor speed, posture, gait, and coordination are generally preserved. This has important clinical implications for the assessment and management of wandering behavior. Gait and balance are the fundamental physical skills which support independent mobility and thus wandering. Any patient with a history of wandering requires both gait and balance assessment. The purpose of assessment is to document the ability of the patient to ambulate safely. The extent of preserved safe ambulation behavior is the fundamental skill, second only to memory, underpinning "safe" wandering (i.e., the ability of the patient to negotiate the environment without harm to self or others).

With the exception of PD, normopressure hydrocephalus, and cerebral infarction with focal damage to relevant motor areas, abnormal gait or balance is not likely to be dementia-related until late in the course of the disease. Thus, examination for alternative explanations should be sought and resulting causes treated if such abnormalities are identified.

In the cognitively impaired patient gait and balance assessment may require modification to compensate for the inability of the individual to respond appropriately to verbal direction or gestures. In such a circumstance, discrete observation of the patient in a natural daily setting can substitute for specific testing of gait and balance. Since evidence suggests that wandering occurs in time-frames unique to each individual, gait and balance assessment timed to coincide with the patient's most active daily period will yield the most useful information.

Few gait and balance assessment tools with established reliability and validity exist for use with the elderly, and none have been specifically constructed for assessment of the cognitively impaired elder. In the absence of specific tools, those developed by Tinetti (1986) are widely used in clinical contexts and can be readily adapted to the needs of the cognitively impaired. While comprehensive gait and balance assessment will alert staff to specific mobility skills deficits, such testing cannot predict the success of preventative and adaptive safety measures for patients who wander. Anecdotal evidence suggests that many wanderers have superior mobility skills, can negotiate complex obstacles, and will persist in hazardous wandering despite safety measures. Recent empirical evidence suggests that, while a regular exercise program can increase muscle strength and stamina in AD, regular exercise has no significant effect on overall functional ability (Francese, Sorrell, & Butler, 1997).

The Tinetti gait assessment tool (Tinetti, 1986) covers nine areas of function basic to walking, including step height, length, symmetry and continuity, path deviation and turning while walking. The Tinetti balance assessment tool (Tinetti, 1986) covers sitting and standing balance, eyes closed balance, turning balance, rising, sitting, bending, and reaching. When testing gait and balance, observe the patient in an obstacle-free hallway and continue natural observation long enough for the severely cognitively impaired patient to demonstrate the required skills without verbal cueing. Less impaired patients may be able to respond to several of the simple commands required in both tools.

With a wandering patient it is critical to document as much of the data from formal assessment as possible, along with anecdotal accounts from staff and family of preserved mobility skills. For example, many wanderers, very late in their disease process, can climb and will be observed by staff climbing over chairs, up ladders, or onto ledges and tables. In addition, some patients had occupations in which climbing, balancing, and getting underneath or between structures was part of their daily work and remains part of their activity in institutions. Documented accounts of these preserved skills can help in the planning of individual environments free from known hazards.

With the cognitively impaired patient, balance and gait testing needs to be repeated at regular intervals or when cognitive status deteriorates from previous levels. While no standard time frame for re-evaluation has been established, periodic testing ensures the regular and systematic assessment of gait and balance as cognitive ability declines and provides a baseline against which to compare current function. Since the performance of motor skills is closely related to visuospatial ability, any deterioration in sensory capabilities or environmental change will also impact gait and balance, at least in the short term, and repeat testing should be considered.

In cognitively impaired wandering patients, pre-existing sensory loss of any type can complicate assessment. In addition, sensory loss interferes with communication and leaves fewer uncompromised options available to both subject and assessor. In those with cognitive impairment, even minimal assessment of sensory function is challenging and is based more on the subject's ability to function in the environment than on the results of objective testing. Wandering patients may not be able to remain still for long enough to complete formal testing of sensory function.

People with AD experience visual losses, specifically problems with color vision, depth perception, eye movements, contrast sensitivity, and higher-order visual perception (M. F. Mendez, M. A. Mendez, Martin, Smyth, & Whitehouse, 1990). In assessing vision, one looks for indications that the patient may be reading signs or books aloud, or that they appear clumsy and are bumping into furniture.

Hearing assessment in the wandering cognitively impaired patient relies heavily on knowledge of the patient's prediagnostic hearing ability. Wanderers frequently do not respond to voice instructions, even when their hearing appears to be intact. This seeming oblivion may have to do with lack of recognition of their name, the inability to distinguish individual sound amongst background noise, or a high level of preoccupation with their wandering behavior. None of these possibilities have been empirically tested. Clues about hearing ability can be obtained by watching for signs that the wanderer is hearing and responding to sound. For example, the patient may obviously enjoy music by tapping the feet or hands or singing along. Where there is existing hearing loss, three simple clinical tests using a tuning fork may help determine the type of hearing loss—the Rinne, Weber, and Schwabach tests, but each of these is highly dependent on the patient's ability to respond verbally to commands (Gallo, Reichel, & Andersen, 1995).

Cognitively impaired patient may experience deficits with taste and smell, but are often unable to report them. Wanderers will frequently appear with bruising related to bumping into things and have lost the ability to determine danger where there is hot water or electrical appliances. Some cognitively impaired persons also develop pica and many persons with late-stage AD will eat voraciously without regard for taste.

Crude assessment of kinesthetic sense in wanderers is possible during gait and balance testing by observing for ability to maintain sitting and standing balance and to recover from a gentle push against the shoulder. Fear of falling is apparent when a patient reaches out or braces, even when induced disequilibrium is slight. Wanderers are generally at less risk of kinesthetic deficits than less active or immobile patients because frequent walking stimulates proprioceptive and vestibular function.

Although assessment of sensory abilities in all modalities is important for safety considerations, anecdotal evidence gained from observations during our research suggests that some deficits may actually contribute to particular patterns or rhythmic parameters of wandering. However, the specific contribution of various sensory deficits to aspects of wandering behavior remains to be determined.

7.17.7.2.2 Mediating factors

Unlike foundational abilities, which are necessary for safe ambulation but may not actually affect the amount or type of wandering, mediating factors may play an active role in shaping this behavior. These factors include: cognitive strengths and deficits; mood, affect, agitation, physical discomfort; and personal patterns and preferences. As assessment of cognition, mood, affect, and agitation are the focus of other chapters, our discussion here is limited to personal patterns and preferences and physical discomfort.

To determine a wanderer's personal patterns and preferences, a personal interview and discussion with the patient and the primary informant is essential. Since patterns are laid down over time and stored in remote or procedural memory, many persist in the presence of recent memory loss and can be understood in the context of the patient's prediagnostic lifestyle and occupation. For example, a patient who once owned a chicken farm spent the early morning out in the yard making "shooshoo-ing" sounds and gesturing as if throwing seed down. Any attempt to interrupt the patient during this time resulted in an aggressive outburst. This type of habit behavior has been described as "agenda" behavior (Rader et al., 1985). Knowledge of such patterning can assist in understanding the origin and role of a behavior in a patient's life and bring new meaning to seemingly irrational actions.

Preferences, too, are long-standing and thus likely preserved late into a dementia. One of the most enduring preferences is that of food and many patients in advanced stages of the disease cannot choose between foods but will reject food they have always disliked. The role of personal patterns and preferences for daily routines, food, clothing, and any other aspect of the patient's environment is needed to understand their role in shaping wandering behavior. Such evaluation can greatly inform the design of effective targeted intervention strategies.

Although evaluations of efforts to preserve enduring life patterns and preferences for effects on parameters of wandering behavior are lacking, attention to such preferences has been used to reduce the problems arising from wandering. In a case study by Donat (1984), often repeated behavioral patterns were accommodated by reassigning a patient to the room most frequently entered and moving its then current occupant to new quarters. For the wanderer, this room reassignment eliminated exposure to the unhappy response her intrusive behavior precipitated from staff and the other resident; the gain for the other resident was exemption from unwanted intrusions into her private space.

Ability to accurately identify, personally address, or effectively communicate physical discomfort is hampered by cognitive impairment in wanderers. Increased restless or pacing behavior can signify such meaning. Common discomforts can be avoided or reduced in most cognitively impaired patients using systematic toileting, feeding and resting schedules. Food acceptance charting and routine weighing can aid in assessing hunger. Enforced daytime resting and napping, while offering respite from walking, may exacerbate circadian rhythm disturbance and create an artificial "need" for restraints. Observation and recording of the frequency and length of daytime napping and night sleep may assist in determining fatigue.

Although many wanderers are in better physical condition than nonwandering counterparts, they are not immune to arthritis, angina, and other acute and chronic conditions which cause pain. Additionally, wandering, by virtue of high activity levels, can aggravate certain conditions, such as arthritis, and precipitate others, such as foot blisters. Pain may account for noticeable changes in activity level.

Two instruments can assist in the assessment of discomfort in wanderers. (i) The Discomfort Scale-Dementia of the Alzheimer's type (DS-DAT), developed to assess for nonspecific discomfort (Hurley, B. Volicer, Hanrahan, Houde, & L. Volicer, 1992). The DS-DAT contains nine behaviors which reflect presence or absence of discomfort. Good construct validity (coefficient alpha = 0.77, $p < 0.001$) and test–retest reliability (0.60, $p < 0.001$) were reported on data from serial observations of 20 subjects with conditions known to cause discomfort. Inter-rater reliability ranges from 0.86 to 0.98 across four observations of five to nine subjects (Beck, personal communication, 1997). Again, this instrument was developed for the purpose of evaluating behavior captured in natural settings on videotape, but could be readily adapted for clinical use. (ii) An instrument for assessing pain that may be appropriate for use with wanderers is the Wong–Baker Faces Pain Rating Scale (FPRS). Useful for rating both presence and severity of pain, this series of six line-drawn faces was developed to evaluate pain in children who are at least three years old (Wong & Baker, 1988). In a sample of 97 adults (aged 21–65 years), Cason and Grissom (1994) report that the FPRS correlated with perceived pain intensity ($r = 0.79$) and a visual analog scale (0.67). Although reports of use with demented adults were not located, the fact that the FPRS is targeted to three-year olds suggests that it does not exceed the cognitive capacity of most demented elders (Thornbury, 1992).

7.17.7.3 Assessment of Wandering Outcomes

Outcomes most frequently associated with wandering are falls and elopement. Other outcomes of clinical interest include social functioning, weight loss and nutritional status, sleep and fatigue. Assessment concerns applicable to each are discussed in the following sections.

7.17.7.3.1 Falls

The management of highly mobile, wandering nursing home residents is a particular challenge because their increased mobility levels predispose them to increased extrinsic (e.g., tripping) and intrinsic (e.g., dehydration, fatigue) hazards (Berg & Cassels, 1990; Whall, Gillis, Yankou, Booth, & Beel-Bates, 1989). While mobility is crucial to functional ability and continued well-being during aging, associated falls are critical incidents for the elderly because of their serious immediate and long-term effects (Hogue, 1984; Rubenstein et al., 1994; Vallarino & Sherman, 1981). Falls by the elderly, "or events in which the patient came to rest on the floor from a lying, standing or sitting position" (Heslin et al., 1992) are widespread and well documented. Etiology, risk factors, and management are common research foci.

Limitations in mobility place cognitively intact individuals at higher risk of falls and fractures and the complications associated with them. A higher incidence of falls has been demonstrated among the institutionalized aged (25–61%) than among the community-based aged (Campbell, Reinken, Allan, & Martinez, 1981; Foerster, 1981; Hogue, Studenski, & Duncan,1990; Morris & Isaacs,1980; Overstall, 1978; Sehested & Severin-Nielsen, 1977; Tinetti, 1987; Tinetti et al., 1988; Wild, Nayak, & Isaacs, 1981). However, fall rates and fall-associated injuries vary greatly among and between hospitals and long-term care facilities and are highly dependent on fall reporting methods (Kanten et al., 1993). An epidemiological review of all large-scale published nursing home studies determined a mean incidence rate of 1.5 falls per bed per year (range 0.2–3.6 falls) (Rubenstein et al., 1994). Nursing home studies of the outcome of falls identified serious injuries such as hip fractures, cerebral contusions and hematomas as occurring in 3–6% of the subjects who fell (Morse et al., 1985, 1987; Tinetti, 1987).

The etiology of falls can be characterized as either extrinsic or intrinsic (Berg & Cassels, 1990). Extrinsic factors are general environmental factors, for example, lighting levels, time of day, placement of furniture, type of floor coverings, cleanliness of floors, and type of footwear worn. Critical intrinsic factors include the aging process itself, the presence of disease, increased general frailty, impaired postural control, limitations in mobility, poor vision, psychotropic medication intake, and gender (Barbieri, 1983; Cook, Exton-Smith, Brocklehurst, & Lampert-Barber, 1982; Louis, 1993; Tinetti, 1986; Wild et al., 1981). The relative contribution of each of these intrinsic factors to both fall risk and frequency has not been clearly elucidated.

Dementia can contribute to falls (Buchner & Larson, 1987; Janken et al., 1986; Morse et al., 1987; Nevitt et al., 1989). In a number of studies related to falls in nursing homes, cognitive impairment is the most important and frequently documented risk factor identified (Buchner & Larson, 1987; Reinboth & Gleidenvand, 1982; Rubenstein et al., 1994; Tinetti et al., 1988; Walshe & Rosen, 1979). In several studies, cognitive changes are associated with impaired gait, impaired balance, and wandering (Kippenbrock & Soja, 1993; Morse et al., 1985, 1987). Although thought to be an important factor in falls, the association between wandering and falls has not been well documented.

Conversely, elderly residents rated by nursing staff as alert had the greatest number of falls (Kalchthaler, Bascon, & Quintus, 1978) and a low incidence of mental confusion was found among residents involved in falls. Based on a study of 60 institutionalized women with Alzheimer's disease, researcher's concluded that falls were related to a decline in overall "vigor" in those who had been active (Brody et al., 1984).

While the relative contribution of critical intrinsic factors in the etiology of falls has not been clearly elucidated, the presence of a dementing process remains the most important and frequently documented intrinsic risk factor identified. Early work by Algase (1992b) examined antecedents and consequences as pacers for wandering cycles and determined that wandering is most likely to occur when the residents' activity is unfocused and solitary (52% of 2405 wandering episodes, $n=31$).

Retrospective chart auditing can establish incidence rates only for reported/recorded falls. While such data will provide a baseline, it is critical to determine actual rates more accurately by the systematic observation of at-risk patients. Examination of the at-risk patient for evidence of bruising and cuts caused by falling, and the comprehensive assessment of reports of pain-related behavior in cognitively impaired wandering patients, for example, wincing and limping, can reveal that a patient has had an unseen fall. The early identification of at-risk patients at the time of their admission to a facility, including previous fall history, drug history, and physical examination, is recommended (Brungardt, 1994).

7.17.7.3.2 Elopements

Virtually all clinicians who work with wanderers are aware of elopement as a general hazard and have experienced the wiliness and persistence of some wanderers in successfully escaping the boundaries of their prescribed area. However, there are also those wanderers whose exits are accidental and whose spatial disorientation prevents them from recognizing that they are lost or disables retracing their steps for a safe return. While researchers have counted a variety of behaviors to signify elopement attempts (approaching exit doors, touching or manipulating door knobs, asking to leave, etc.) (Gaffney, 1986; Hussian, 1982; Namazi, Rosner, & Calkins, 1989), specific behavioral predictors for either "type" of elopement are unknown. Observing both antecedents and consequences of an individual's exit attempts can illuminate their unique pattern and thus inform the design of individualized interventions. Due to nursing home reforms contained in the Omnibus Budget Reconciliation Act (OBRA), the use of restraints to prevent elopement is increasingly challenged, legally and empirically (Evans & Strumpf, 1989). Strategies that are less restrictive and operate more passively, such as alarms, are preferred.

7.17.7.3.3 Social functioning

While it has been suggested that wanderers were formally more sociable than nonwanderers (Monsour & Robb, 1982), the social functioning of wanderers is severely inhibited by their marked memory problems, impaired linguistic communication skills, and disinhibition. Assessing social behavior in the severely cognitively impaired is best accomplished by observation of the frequency and quality of interactions with staff, visitors, and other residents. The Minimal Social Behavior Scale (Dastoor et al., 1975) can be used to determine preserved aspects of 1:1 social interactive ability but does not address aspects of social behavior such as the ability to listen and respond appropriately to conversation, the ability to share an activity with others, and the ability to initiate social behavior.

As wanderers become more severely impaired, their ability to reach out and connect with others diminishes. Both staff and other patients frequently find wanderers irritating to deal with because they are forgetful, no longer adhere to social conventions, and unwittingly invade the personal space and privacy of others. Wanderers were the least favored patients in several surveys of caregivers (Lanceley, 1985; May, 1993). Surveys of caregivers and intimates of dementia sufferers indicate that visiting and spending time with a wanderer is a frustrating and difficult experience. The outcome of this potent combination of factors is the further isolation of the wanderer from others in the environment, which may impact the length of time a wanderer spends alone, which may in turn impact parameters of wandering behavior.

The comprehensive assessment of social functioning includes a detailed account of the patient's previous social network and family system and descriptions of the nature and purpose of current relationships (Zarit, Perlin, & Schaie, 1993). A wanderer is limited socially by several factors: (i) the inability to control or modulate their own activity levels and (ii) the loss of linguistic communication ability to the extent that others have difficulty listening to, interpreting, and responding to the wanderer's speech. Thus it is difficult for a wanderer to initiate and maintain social interaction unless another person is able to keep pace with them and tolerate a generally increased activity and a high level of impaired communication.

To date, most research on linguistic communication in dementia has focused on the identification and etiology of deficit rather than preserved functional skills. Several studies support the position that severely cognitively impaired nursing home residents may be capable of greater functional communication competence than has been thought previously (Murray, Marquardt, Richardson, & Nalty, 1984; Slauson, Bayles, & Tomoeda, 1987). Assessment of the preserved linguistic communication skills of the patient will assist in determining the type and nature of interaction the patient has the capacity to take part in. Several scales have been specifically developed for this purpose, including the Communication Observation Scale for the Cognitively Impaired (Tappen, 1988) which focuses on broad categories of impaired function such as the presence or absence of aphasia, blocking, perseveration, talkativeness, meaningless sentence production, and poverty of speech. Since problematic wandering appears to be associated with more severe levels of cognitive impairment, the majority of persistent wanderers will tend to have marked linguistic communication deficits.

A prime function of staff is to nurture the enduring relationships the patient has and to instruct others in ways to spend meaningful time with the patient. One simple way of doing this is to encourage others to walk with and accompany a wanderer, rather than expecting a wanderer to sit down and visit. Maintaining simple conversation focused in the here and now can assist in orientating the wanderer and increasing the interactive climate and expectations of the patient to remain social. However, little is known about the impact of expected social interaction and interactive pressure on levels of anxiety in wanderers, or on pattern and rhythm of wandering.

7.17.7.3.4 Weight loss and nutritional status

Patients with dementia have difficulty obtaining, preparing, and eating food. Patients who wander tend to have a higher lean muscle mass than less active patients, while requiring a higher calorie intake to support wandering activity. While overnutrition can be a problem early in the dementing process, the more likely scenario for a wanderer in the long term is a profile of undernutrition. Overnutrition may result from the inability of the patient to choose appropriate foods and uncontrolled eating. Undernutrition related to wandering is multifactorial resulting from the inevitable wasting related to dementia, the inability of the patient to sit still long enough to eat and drink adequately, changes in the condition of the mouth and teeth, increased activity levels occurring simultaneously with interrupted sleep patterns, and the inability of the patient to manipulate utensils. Severely cognitively impaired individuals may also spit, gag and stuff their mouths with food.

It is essential to calculate the weight and body mass index of the wandering patient and compare these measures to normative measures. The weight of a wanderer requires monitoring at regular intervals to prevent significant weight loss of going unreported. The nursing home standard of monthly weightings may be insufficient for wanderers. A dietary history including known allergies, food preferences, and usual eating times will assist in food selection and meal planning. Wanderers require increased calorie and fluid intake to balance the energy depleted in excessive motor output. A simple pedometer secured on the patient's clothing can give an estimate of miles traveled during waking hours and permit the calculation of calorie requirements for the patient in order to maintain current body weight. However, gait quality may affect the accuracy of pedometers as most work on impact and a more shuffling gait is common among wanderers. Assessment of the mouth and teeth, and correction, where possible, of mechanical problems associated with eating, will facilitate intake.

7.17.7.3.5 Fatigue and sleep disruption

Sleep disruption routinely occurring over extended time periods results in fatigue. In the wandering patient, fatigue levels may also be increased by persistent levels of physical overactivity. A characteristic anecdotal activity of wanderers is day-time napping but little empirical evidence exists to support this (Snyder et al., 1978). Sleep observation charting, at intervals of 30 minutes, will provide a reasonably accurate indication of the pattern of night waking, total uninterrupted sleep time, and daytime napping experienced by a wanderer (Bliwise, 1994), however, this method is staff intensive. Other methods of sleep assessment are both costly and cumbersome and therefore not yet clinically viable with this population.

7.17.8 INTERVENTION STRATEGIES

While the literature on wandering is certainly not vast, almost as many papers address interventions as discuss all other aspects of the behavior. Many suggested interventions have only clinical evidence to support their value. However, some have been tested empirically, but only a few of these have been refined through replication studies. Unfortunately, whether based on clinical experience or research, few interventions are theoretically driven or tied to putative etiologies for wandering. In the following sections, goals for treatment and intervention of wandering, as well as general health and safety considerations for wanderers, are outlined. Information on the range of tested and untested strategies and interventions are then summarized.

7.17.8.1 Goals for Treatment and Intervention

Overall goals for treatment and intervention with wanderers are: (i) assuring safety, (ii) preserving abilities, (iii) maximizing comfort, (iv) minimizing restriction, and (v) eliminating or reducing negative effects of wandering for the wanderer, other residents, and staff. Achieving these goals may entail efforts to reduce, redirect, contain, or redistribute wandering behavior itself. Further, strategies for achieving one goal can, at times, present challenges for attaining another. Prioritization of goals, which should include known personal preferences of the patient and involvement of both family and caregivers, can assist in resolving such conflicts. However, since knowledge of the etiology and purpose of the behavior remain limited at this time, measures designed to either restrict or facilitate the amount of wandering have little empirical basis and should be undertaken with extreme caution. A general rule of thumb is that such measures may be practiced if they do no harm, but careful monitoring to assure such is mandatory.

7.17.8.2 General Health and Safety Considerations

Sustained effort needs to be made to maintaining the physical condition and emotional well-being of the wandering patient. All possible measures for environmental safety need to be instituted to minimize or eliminate hazards associated with falling and elopement. In addition some simple environmental manipulation may assist the wanderer in way-finding and environmental interpretation.

Overall goals for maintaining the physical condition of wanderers are (i) ensuring adequate hydration, (ii) ensuring adequate nutrition, (iii) preventing exhaustion, (iv) minimizing circadian rhythm disturbance, (v) preserving skin integrity, and (vi) monitoring the dosage and undesirable effects of prescribed medications. Overall goals for promoting emotional well-being for the wanderer include (i) engaging the person in meaningful, supervised, and structured activity which provides sensory stimulation; (ii) creating regular opportunities for 1:1 purposeful communication at the person's level of comprehension; and (iii) preserving elements of previous meaningful life activities.

Overall goals for ensuring the physical safety of the wanderer are (i) removing safety hazards from the environment, (ii) enhancing lighting, (iii) preventing elopement, and (iv) balancing the level of stimulation in the environment. Since wanderers are cognitively impaired, aspects of the environment will grow increasingly unclear to them. Measures which may improve the functional ability of wanderers in negotiating their environment include (i) providing redundant cueing; (ii) decorating rooms with relevant personal items and photo identification; (iii) displaying orienting information in multiple, prominent places; and (iv) using rooms for a single, clear purpose.

7.17.8.3 Tested Techniques for Altering Wandering Behavior

7.17.8.3.1 Exercise

On the premise that directed energy expenditure could dissipate or reduce spontaneous wandering, Robb (1987) tested a program of exercise. In a quasiexperiment involving a multiple pre- and post-test design, the hypotheses that exercise would act to reduce the length of time spent in wandering, reduce overall energy expenditure, and improve night time sleep behavior in subjects with a medical diagnosis of dementia were tested. Twenty male subjects (aged 50–87 years) received 12 weeks of programmed outdoor exercise for two hours per day five days per week. Elements of wandering behavior, for example, change in location, time spent in each location, and limb and head movement, were measured during the day and at night prior to the intervention, at eight weeks into the intervention, and six weeks postintervention using behavioral mapping. All subjects received initial fitness and cognitive testing. Effort-induced physical harm was prevented with pulse checks and close observation.

Planned exercise had no significant effect on daytime wandering. However, reductions in night-time wandering were significant for number of locations visited and total time in motion. Serendipitous improvements in range of motion and energy expenditure were also reported. Despite its promise for reducing night-time wandering, no replication studies or clinical reports using exercise were found.

7.17.8.3.2 Cueing

The use of signs, whether composed of words, pictures, graphics, or familiar objects or pictures, has been widely advocated clinically to improve the spatial orientation of cognitively impaired persons. While this strategy has not been examined with regard to effect on overall amount or type of wandering behavior, it has been evaluated for its ability to enhance spatial orientation in the cognitively impaired.

In one experimental study, baseline route navigation and four location-to-location comparative trials were used to determine the effect of sign-post cueing on navigational ability in a sample of 20 spatially-disoriented long-term care residents (Cooke, Algase, & Terpenning, 1993). The sign-posting consisted of large, primary-colored, eye-level signs in simple shapes, such as circles, squares, and hexagons, or in shapes favored by or meaningful to the resident, such as cats or flowers, and labeled in large type. Sign-posts were strategically placed in doorways and corridors directing subjects to relevant locations, for example, the dining room, bathrooms, and their own rooms. Subjects navigated each of four routes sequentially without directional prompting but with occasional verbal reminders of the target location. Time to navigate the route, hesitancies, errors, and overall points scored were recorded for each route and all routes combined. Results of the study demonstrated that sign-posting, regardless of design, did not increase navigational ability.

7.17.8.3.3 Lighting

Several empirical studies have examined the effect of light on activity levels, defining wandering as one of a number of expressions of agitation in dementia. Early work by Evans (1987) identified the phenomenon of "sundowning" in which demented individuals become more agitated and restless with declining light levels in the late afternoon. Cohen-Mansfield et al. (1989) detected temporal patterns of activity disturbance over a 24-hour day in demented patients. Seasonal variation exists in agitated behavior (Bliwise, 1994; Bliwise, Carol, Lee, Nekich, & Dement, 1993), with agitation increasing in the darker winter months. In a Japanese study (Okawa et al., 1989), both morning and evening bright light treatment deceased agitation behavior. More recently, Lovell, Ancoli-Israel, and Gevirtz (1995) administered bright light at 2500 lux levels to six demented subjects (mean age = 82 years) for two hours in the morning for repeated 10-day periods in an ABABA design. Results indicated a significant difference in agitation levels on light-intervention days.

In the only known study of light directed at wandering, three light levels were specifically manipulated (baseline, bright light, and dim light simulating sundown) in a nursing home lounge outfitted for the study (Algase, 1997a). Ten cases were studied for three two-hour periods weekly over a six-week period in random assignment to either an ABAACA or ACAABA design; the second baseline week was intended as a washout period for any carryover effects. The time period was individually selected to match each case's most active period of the day. Although data analysis is incomplete at this time, preliminary results indicate that, regardless of lighting condition, wandering in the lounge was minimal. Logically, factors other than light account for the quite dramatic decrease in wandering observed. Simplicity of the lounge environment, which was completely accessible visually from any vantage point in the room and controlled most sources of stimulation, is the speculated explanation.

7.17.8.3.4 Social interaction

Interventions for wandering addressing aspects of social interaction are primarily related to restraint-reducing efforts. Many programs designed to increase and facilitate interactive social behaviors in the demented give anecdotal descriptions of the reduction in agitation and wandering produced by increased social opportunity and stimulation (Arno & Frank, 1994; Gerdner & Swanson, 1993; McGrowder-Lin & Bhatt, 1988; Mintzer et al., 1993). However, only one empirical study has so far explicitly sought to impact wandering.

Goldsmith, Hoeffer, and Rader (1995) report a test of Rader's (1987) "approach" to wandering (which includes steps to identify potential wanderers, programs and activities for safe ambulation, decreasing use of restraints and psychotropic medications, interaction strategies for managing exiting behavior, creating a safe and supportive physical and psychosocial environment) taught to nursing staff. The study used a single case design with a four-week preintervention phase, a four-week intervention phase, and a six-week postintervention phase. Use of medications and restraints decreased during the intervention phase, but medication use began to rise postintervention. Decreases were associated with increased Physical Self-maintenance scores. This approach had no demonstrable effect on problematic wandering (ambulating alone, exit-seeking while alone, alone in unsafe locations). During all phases of the study, 80% of observations documented a lack of social interaction between staff and subject, except during ADLs. The study was poorly controlled in that once staff were trained, it is theoretically possible, but unlikely, that they did not revert to their pretraining behavior during the postintervention phase of the study. The extent of reversion to pretraining habits and the amount of retraining required over time were not considered.

A recent study utilized a multiple case study design to examine the effect of a systematic, structured nurse–resident communication style on pattern and rhythm of wandering behavior in severely cognitively impaired nursing home residents (Beattie, 1996). An identical quasi-experiment was embedded within each case study as an interrupted time-series with multiple replications and nonequivalent dependent measures. The intervention was a modification of the Heron Six-category Intervention Analysis (Heron, 1976). Results were highly individual across cases, showing no consistent significant effect of the intervention.

7.17.8.3.5 Drug therapy

Older people have qualitative and quantitative differences from younger people in absorption, distribution, metabolism, and excretion of drugs. The wide use of drugs to control difficult behaviors associated with dementia has increased the potential for negative drug reactions. In the cognitively impaired patient, the management of drug therapy is a particular challenge because patients are frequently unable to report undesirable effects, and many patients have multiple pathology requiring concurrent medication.

The dangers of polypharmacy in the elderly are well known. In the cognitively impaired patient the general rule of "less is better" usually applies. A minimalist approach to medications is particularly important when trying to manage difficult behavioral symptoms and tease apart factors contributing to them. In addition, many cognitively impaired patients have difficulty accepting and swallowing medication and compliance must be carefully monitored. Regular and systematic review of medications can prevent some problems and minimize the impact of others. Wherever behavioral change occurs unexpectedly, or unusual behavior persists over a time period longer than a week, it is essential to consider the role of current drug therapy in the clinical presentation of the patient.

Two groups of drugs that are commonly prescribed in to patients with cognitive impairments may have a therapeutic effect on wandering: neuroleptics and benzodiazepines. The neuroleptics are most commonly prescribed for the treatment of agitation and hyperactivity, and are often differentiated on the basis of their undesirable effect profiles. The two major classes of neuroleptics are the phenothiazines (e.g., chlorpromazine and thioridazine) and the butyrophenones (e.g., haloperidol). In general the phenothiazines tend to be quite sedating and are associated with hypotension. Thus in the wandering patient the risk of circadian rhythm disruption, increased gait instability and fall risk, and hypothermia secondary to accidental elopement must be considered. The butyrophenones cause less sedation and few hypotension problems but are more frequently associated with neuroleptic-induced Parkinsonism, characterized by drooling, mask-like facial expression, muscular rigidity, and gait changes. Tardive dyskinesia (TD), an irreversible syndrome involving involuntary movements of the tongue, mouth, face, and neck, is usually associated with long-term neuroleptic use. In some cases, agitated behavior can be exacerbated by neuroleptic treatment so drug treatment should be conservative and time-limited. Over 90 studies of neuroleptic treatment of agitation in the elderly have been reported. Salzman (1987) and Sunderland and Silver (1988) report very similar levels of acceptance and behavioral control, with 70–80% of patients having none or minimal undesirable effects.

The benzodiazepines (e.g., diazepam, oxazepam, alprazolam, lorazepam) are frequently prescribed for symptoms of insomnia and anxiety in the elderly. To the extent that wandering is based on anxiety, they may be effective in its management. There are many age-related changes in response to this group of drugs, primarily due to pharmicokinetic alterations in drug metabolism which result in extended duration of action and lead to an accumulation of side effects (Greenblatt, Divoll, Abernethy, Harmatz, & Shader, 1982). Lorazepam has an uncomplicated metabolic pathway, but has been associated with specific memory impairments (Preston et al., 1988) and is thus a poor choice for the cognitively impaired patient.

7.17.8.4 Tested Techniques for Addressing Undesired Outcomes

Although several putative outcomes of wandering, discussed earlier, are thought hazardous, only one has received the attention of researchers. Reduction or control of egress has been the chief objective of such research. While not concerned with affecting the overall amount, distribution, or type of wandering, these studies focused mainly on reducing successful exits or exit attempts of known wanderers from their assigned unit or permitted range for free movement. The extent to which such exits or attempts occur during actual wandering, as compared to other self-directed locomotion, i.e., direct ambulation, remains unexamined. Three techniques have been tested: behavior modification, camouflage, and perimeter control devices.

7.17.8.4.1 Behavior modification

Principles of learning are frequently incorporated into planning wandering management, for example, rewarding constructive behavior and changing the consequences of the behavior (Hussian & Davis, 1985; Stokes, 1986). However, there are few examples in the literature of controlled, systematic behavior modification. Early work by Hussian (1982) investigated the effect of controlled stimuli and rewards on wandering patterns. The wandering behavior of three subjects (mean age = 73.4 years; mean length of hospitalization = 13 months) was conditioned using two sets of cardboard stimuli: orange rectangles and blue circles. Attention to the orange rectangles resulted in reinforcement with food; attention to the blue circles resulted in the aversive stimulant of an unpleasant noise. During conditioning, baseline data on ambulation behavior were obtained.

Following conditioning, the stimuli were affixed to walls where ambulation was either encouraged (orange) or discouraged (blue). Subjects were systematically observed for periods of 30 minutes. If no contact with the blue areas was made, subjects were rewarded with food. If contact with the blue areas occurred, subjects were returned to their point of origin without consequence. Over time the stimuli were faded by size reduction and eventually removed from the environment.

Mean number of entries into the designated blue trespass area was reduced across all subjects following conditioning by rates ranging from 13 to 100% per 30-minute period. However, booster sessions were required by all subjects at three months and the stimuli were replaced on the walls. Four booster conditionings were required over the 12-month period following initial conditioning. Eventually fading resulted in re-emergence of wandering to preintervention levels. While results of this study clearly demonstrate that wandering can be altered by environmental cueing, the effect on wandering will persist only as long as the cueing is maintained. Given the pattern of known decline in memory and visuospatial deficits in AD, the frequent reconditioning needed to maintain cueing effectiveness is not surprising. Using this method of behavioral control, cueing may need to be increased in intensity and frequency as cognitive functioning declined in order to achieve the same behavioral change. Further studies replicating Hussian's work would benefit from greater specification of level and stage of AD and finer gradation criteria for the fading of stimuli.

7.17.8.4.2 Camouflage

Problems with color vision, depth perception, eye movements, contrast sensitivity, and higher-order visual perception are known visual deficits associated with Alzheimer's disease (Mendez et al., 1990). Hussian and Brown (1987) proposed that these deficits might result in a misperception whereby a two-dimensional grid pattern, fixed to the floor with tape, would be seen as three-dimensional and, thus, unstable. If so, demented subjects may be hesitant to walk upon it and, if strategically placed in front of doorways, grids might reduce exits and exit attempts.

The effect of several different grid patterns made of low-contrast tape when applied to the floor in front of emergency doors were examined for effect on exiting behavior in a sample of eight male subjects with senile-onset, primary, degenerative dementia. Baseline data on attempted exits indicated that an attempt was associated with exit-door contact in 98% of observations. All grid patterns were effective in reducing exit attempts for all but one subject, who was never deterred by any pattern. Subjects did not cross the grid in 70% of their exit attempts.

Several researchers have attempted to replicate Hussian and Brown's results using a variety of color combinations and tape patterns and improvements in design of the original work (Chafetz, 1990; Hamilton; 1993; Hewawasam, 1996). Most were ineffective or results were equivocal. Inability to achieve success was attributed to factors such as confounding effects of medication or strength or "dose" effect of the grid intervention (i.e., grid insufficiently aversive to overcome enticing view through glass doors). However, grid patterns may be effective for patients diagnosed with AD due to associated problems in depth perception, but are not successful with other dementias (Hewawasam, 1996).

Based on the visual agnosia associated with dementia, visual barriers (i.e., door knob coverings or other disguising techniques that appear to create an obstruction, but do not actually impede egress through a door) have been suggested as an alternative camouflage strategy. Namazi et al. (1989) tested the effect of seven different visual barriers on resident exit behavior on an Alzheimer's unit. The subjects ($n = 9$; 55% female; mean time since diagnosis = 5.75 years) had similar cognitive abilities as measured by the MMSE (Folstein et al., 1975) and the Short Portable Mental Status Questionnaire (PMSQ) (Johnson & Grant, 1985). Barriers, which varied in color, material, width, angle of placement, and purpose, disguised both the exit and the door knob. Doorknob concealment was 100% effective in preventing exit behavior in all subjects. However, visual-spatial testing of subjects was not standardized and the exit behavior of subjects and their anxiety levels were not discussed.

In a replication of Namazi's work, the possible attraction of windowed doorways, which may have confounded efforts to replicate the original grid studies, was taken into account (Dickinson, McLain-Kark, & Marshall-Baker, 1995). A cloth panel matching the emergency door color and covering its panic bar was the visual barrier tested. In addition, a miniblind was used to control the view from a window in the door. A sample of seven ambulatory demented subjects (five male; two female; aged 70–87 years) with a history of exiting behavior were chosen from one dementia care unit; no other cognitive characteristics of the sample were reported. Three conditions were tested during a fixed time frame: closed miniblind alone, cloth panel alone, and both miniblind and cloth panel. After obtaining a one-week baseline count of exit attempts at the door, each test condition, which lasted for two hours per day over a one-week period, was followed by a one-week interval during which the blind was left open, no barrier was in place, and no counts were taken.

Overall, the miniblind alone reduced exit attempts by 44% from the baseline while the cloth panel reduced attempts by 96%. Together, the blind and panel were somewhat less effective (88%), suggesting a learning effect. When examining cases individually, four of the seven were found to have had five or fewer exits attempts during the baseline period. Of these, the blind alone was 100% effective for two cases while the panel alone was 100% effective in all cases. However, two of these four subjects returned to or exceeded their baseline count when the blind and panel were used together. The remaining three subjects accounted for 87% of the baseline exit attempts. The miniblind alone was 43% effective; however, the combined miniblind and panel remained nearly as effective (94%) as the panel alone (95%). Thus, the learning effect among these three cases was not as great. Only one of the three demonstrated an increase in exit attempts from the panel to the combined condition, but the increase was small (from 0 to 4) and still represented less than 10% of the subject's baseline count. Characteristics distinguishing those who made many exit attempts from those who made few were not reported. However, these characteristics may be important to delineate. Since these data suggest that those making fewer attempts may be more difficult to dissuade over time, such characteristics may help identify those whose exit attempts may persist and lead to harm.

7.17.8.4.3 Perimeter control devices

Reports of devices such as alarms, fences, and locks to control wandering began appearing in the literature in the 1970s (Miller, 1976). Many commercial electronic and computerized products now exist to provide perimeter control for wanderers, on the assumption that such devices will warn staff of an impending unsafe exit, or prevent such an exit. Devices generally operate in one of three ways: sounding an alarm when a patient crosses an electronic barrier, creating an electronic barrier by automatic closing of gates, doors, and windows, or tracking the patient via a unit worn on the body (Leach, 1985).

In tandem with the development of perimeter control devices, there has been an increase in sensitivity to issues in the humane and compassionate confinement of individuals with cognitive impairments, such as the right to the Least Restrictive Alternative (LRA), that is, to create a balance where individuals are confined at the lowest level considered appropriate to preserve their safety while retaining the highest possible levels of freedom, independence, and dignity (Ebersole & Hess, 1990). Many early perimeter control devices were large, cumbersome and conspicuous. Because these devices contradicted LRA principles, they were unpopular with relatives and staff. Further, they were likely to attract and be tampered with or removed by wanderers. In addition, concerns for the rights of patients have been expressed by ethicists and patient advocates who view electronic monitoring and alarms as violating the rights of privacy, dignity, confidentiality, and the right to give informed consent (Warrington & Eagles, 1995). Further, many practical problems have been associated with perimeter control devices over time, including inadvertent and purposeful triggering, multiple exiting, keeping devices comfortable and functional on patients, and the generally high costs of installation and maintenance.

Several studies have focused specifically on the effect of an alarm system designed to deter the wanderer and alert staff to a possible elopement, however, these studies did not employ definitions or criteria for the selection of wanderers and were uncontrolled (e.g., Gaffney, 1986). One study by Negley, Molla, and Obenchain (1990) focused on changes on resident behaviors when an alarm system is utilized to prevent elopement. Five ambulatory male subjects (mean age = 68.6 years), with various medical diagnoses and considered wanderers by the subjective assessment of senior medical and nursing staff, comprised the sample. Subjects wore wrist tags that activated an alarm concealed under a mat at the entrance to the ward. Observations totaling 120 hours were conducted at 30 hours per week for 4 weeks, with the test conditions varied each week as follows: (i) door unclosed and no sensor tags worn; (ii) door open, sensor tags worn, alarm off; (iii) door open, tags off, alarm on; and (iv) door open, tags off, alarm off. Results indicated a 67% decrease in attempted door exits between weeks 2 and 4.

7.17.8.5 Wandering Paths or Tracks

Many special care environments designed for dementia sufferers now incorporate specific paths or tracks, both indoor and outdoor, where patients can wander; see Zeisel, Hyde, and Levkoff (1994) for an example. By facilitating wandering in a safe environment, rather than restraining a wanderer, proponents suggest that wanderers would be more content and less aggressive, sleep better, and fall and elope less. While the shape of these walking paths varies from geometric to circular, the design is usually simple and the surrounds peaceful and interesting, with plants, pools, fountains, sculptures, and seats for resting. The pleasant atmosphere and accompanied walking which occurs within such environments are assumed to affect both mood and activity levels positively in wandering patients. Clearly, relatives and staff appreciate being able to visit in pleasant surrounds. However, the approach is atheoretical and disregards potential negative effects of encouraging or heightening wandering. Little research exists that tests the impact of tracks on level of wandering behavior or on wanderers, other residents, visitors, or staff.

An empirical study involving 14 subjects in a specially-designed dementia care unit (Kovach, Weisman, Chaudhury, & Calkins, 1997) explored the association of physical environment with behaviors and care of the demented. The study incorporated a "meaningful wandering path" in the facility design. The path circled a central area allowing continuous movement overlooking activities and involved small travel distances and landmarks, but the specific effect of this design element was not reported. To date, there is no evidence to suggest that such environmental manipulation alters parameters of wandering or benefits the wanderer.

7.17.8.6 Activities Programming

Most intervention studies using programmed activities have been global in intent and eclectic in content. Few have focused on a single systematic intervention targeting a single problem behavior such as wandering. These studies have assumed an unsubstantiated homogeneity among problematic behaviors associated with dementia and thus their clinical applicability and utility is limited (Cleary, Clamon, Price, & Shullaw, 1988).

Only one empirical study to date has explicitly sought to impact only wandering behavior (Goldsmith et al., 1995) with little success. The rationale for using activities to moderate wandering remains atheoretical. Anecdotal evidence suggests that it is difficult to find activities that are age-appropriate, span the abilities of a group of cognitively-impaired people, engage the interest of wanderers, and assure the success of wanderers with the activity.

7.17.8.6.1 Physical and chemical restraint

Physical restraint use by belts, wrist ties, vests, lap trays, and other mechanical devices remains common in wandering and agitation management (Werner, Cohen-Mansfield, Braun, & Marx, 1989), even though no published studies document the supposed reduction of wandering or agitation resulting from the use of physical restraints. Rather, a rebound effect in activity level may occur upon restraint release (Miller, 1975). Prevalence of restraint use is documented at between 18% and 85% in nursing homes (Folmar & Wilson, 1989;

Morrison, Crinklaw-Wianko, King, Thibeault, & Wells, 1987; Zimmer, Watson, & Treat, 1984). While these rates are from studies made before Federal criteria and restrictions for restraint use in long-term care settings were established to improve the quality of life and safety of the residents (OBRA, 1987), no more recent estimates were located. High levels of restraint use have also been found when residents are over age 75 years have a medical diagnosis of organic brain disease (Folmar & Wilson, 1989). Problems associated with restraints include: loss of dignity, urinary incontinence, constipation, muscle atrophy, limb ischemia, increased agitation, strangulation, and, in some cases, death (Beardsley et al., 1989; Werner et al., 1989).

In a post-OBRA implementation study, effects of physical restraints on psychotropic medication use in nursing homes were examined (Werner, Cohen-Mansfield, Karoknay, & Braun, 1994). A retrospective and prospective longitudinal design was used to obtain information about medication use and restraints over a two-year period at seven points in time: four, two, and one month prior to restraint removal; at the time of restraint removal and one, two, and four months after. Subjects (n = 88, 75% female, mean age = 86.3 years, mean length in residence = 5.2 years) were those physically restrained residents of a large nursing home and constituted 62% of the 140 residents who were restrained in the facility. Sixty-one subjects (69.3%) had a medical diagnosis of dementia and 18 had a specific diagnosis of AD.

Results indicated that the proportion of all residents receiving psychotropic drugs decreased from 83% to 70% during the study period, the most significant period of decrease being one month after restraint removal. Those with dementia evidenced the greatest decrease. In this group, medication use decreased from 87% four months prior to restraint removal to 57% four months after restraint removal. These results should be considered cautiously because they represent only one institution. However, adaptations to legal control of restraint use and medication withdrawal was clearly beneficial to those with dementia.

Neuroleptics and benzodiazepines are the most frequently used agents and psychotropic medications are often combined with other centrally acting agents. Zimmer et al. (1984) documented the frequency of interventions for agitation (often including wandering) used in skilled nursing facilities: psychoactive drugs (58% of patients), physical restraints (47%), reality orientation strategies (47%), and specialist psychiatric consultation (38%). In a survey of 1276 geriatric inpatients at 12 Veterans' Administration hospitals, 61% were receiving psychoactive drugs (Prien, Haber, & Caffey, 1985). Fifty-five percent of patients with organic brain syndrome were receiving psychotropics and the most frequently prescribed agents were neuroleptics (44%), antidepressants (11%), and antianxiolytics (10%). Another study of 101 demented inpatients reported that 38% received one psychotropic and 20% received two such medications, with neuroleptics being the agent of choice (Michel & Kolakowska, 1981).

An extensive body of literature, most of it descriptive and anecdotal, addresses the effectiveness of general pharmacological interventions for the control of wandering, agitation, and other behavioral symptoms. Barnes, Veith, Okimoto, Raskind, and Gumbrecht (1982) reported on the effectiveness of antipsychotic drugs for specific behavioral problems in a study of 60 demented subjects. In contrast, Druckenbrod, Rosen, and Cluxton (1993) advised limited use of psychoactive drugs because little data were available documenting the efficacy of their use in the elderly. Nevertheless, neuroleptics remain the mainstay treatment of behavioral disturbance in dementia (including wandering) and the intervention of choice in agitation management, although efficacy studies conclude that the effects are modest at best (Schneider, Pollock, & Lyness, 1990). Haloperidol is the most frequently chosen medication for agitation, restlessness, and wandering in older adults because of its reportedly benign cardiovascular and anticholinergic profile (Weiner, Bruhn, Svetlik, Tintner, & Hom, 1991). On the other hand, many elders are extremely sensitive to its extrapyramidal effects and are already at increased risk of drug-induced TD (Marsden, Milson, Parkes, Pycock, & Tarsy, 1975). For example, Prien et al. (1985) reported that in a small group of AD outpatients with psychotic symptoms, patients could not be maintained on more than 4 mg four times per day of haloperidol because of its extrapyramidal effects.

Neuroleptics have been more widely studied than any other class of pharmacological agent. Most controlled studies of neuroleptic use in dementia have suffered from major methodological flaws, for example, diagnostic heterogeneity was a common feature, methods of assessment were often global, and samples were comprised predominantly of severely demented subjects. In addition, the effects of neuroleptics on core psychotic features as well as behavioral disturbance (including wandering) were not assessed. Only a few published studies used a randomized, double-blind, placebo-controlled design.

Schneider et al. (1990) conducted a meta-analysis of placebo-controlled trials of neuroleptics in wandering, agitated patients with any form of organic brain syndrome. The methodological flaws mentioned previously compromised the utility of the meta-analytic approach to an extent. However, neuroleptics were found to be moderately more efficacious than the placebo (one-tailed $p = 0.004$), with effect size reduced by the high placebo response rate observed in some studies. These response rates may have been due to the inclusion of subjects with very mild behavior change only in order to increase sample size (Devanand & Levy, 1995).

To date no published randomized, double-blind, placebo-controlled study of neuroleptic use (without the concurrent use of other psychoactive agents) to treat wandering in a "pure" AD sample of either institutionalized or community-dwelling subjects have been published. A few reports of neuroleptic–benzodiazepine comparisons in the treatment of behavioral symptoms in demented samples are available.

Several other medications have been reported to be efficacious: trazodone (Pinner & Rich, 1988; Tingle, 1986); lithium (Schneider & Sobin, 1992); carbamazepine (Gleason & Schneider, 1990; Leibovici & Tariot, 1988); valproate (Mellow, Solano-Lozez, & Davis, 1993); propranolol (Pauszeck, 1991); and zolpidem, a nonbenzodiazepine hypnotic (Shelton & Hocking, 1997). Published data from randomized, double-blind, placebo-controlled study of all these medications are sparse. Szwabo, Woodward, Grossberg, and Shenn (1991) postulated that wandering is a response to anxiety and used Alprazolam, a short-acting antianxiolytic, in their 12-week study of 16 wanderers in a nursing home. Wanderers received cognitive testing pre- and postintervention and were placed on four weeks of 0.25 mg twice daily. Alprazolam, titrated to 0.5 mg if needed by a subject. A four-week period without Alprazolam followed the intervention. Behavioral change was monitored using daily ratings of total time spent dealing with wandering behavior and with the Nurse's Observation Scale for Inpatient Evaluation (Honigfeld, Gillis, & Klett, 1966). Results indicated statistically significant improvements in speech and irritability while on the drug, however, drowsiness increased.

Kamei, Oishi, and Takasu (1996) evaluated the use of fasudil hydrochloride, a novel cerebral vasodilator, for night wandering symptoms in two patients with a medical diagnosis of cerebrovascular dementia. Results indicated that wandering behavior disappeared in both patients during eight weeks of treatment, while memory function improved mildly. Wandering began again immediately after the cessation of treatment. Regional cerebral blood flow, measured by P-magnetic resonance spectroscopy and Xe-computed tomography, remained unaltered throughout.

7.17.9 RECOMMENDATIONS FOR FURTHER RESEARCH

7.17.9.1 Definition, Measurement, and Description

Lack of a standard, widely-accepted definition remains a primary challenge in research on wandering. While multiple authors have offered definitions of wandering, the scientific community has made little advance in the discussion and acceptance of a universal definition of the behavior. Reaching such a conceptual consensus would assist researchers in communicating effectively about the phenomenon and move them to issues of measurement and description which are required before interventions can be theoretically supported and rigorously tested. Fundamental questions such as: (i) Do all cognitively impaired individuals wander? (ii) What is the point at which an individual is classified "a wanderer"? (iii) Given that men and women are known to have different spatial abilities, are there gender differences in wandering behavior? and (iv) What are the natural limits to parameters of wandering, such as frequency and time in motion? will remain unanswered until consensus on a definition is reached.

In line with a need for a standard definition is that for valid and reliable measurement techniques for wandering. If there is any "gold standard" it is direct observation, the parameters of which are supported by some theoretical rationale and/or valid typology for wandering behaviors. An additional need, given the known costs and inter-rater reliability concerns with multiple raters in several settings, is for a biomechanical measure that reliably approximates at least some wandering parameters. One aim of our current study is to validate a range of mechanical devices for their utility in estimating frequency and total time in motion. However, there is yet no meter developed for capturing variations among any types or patterns of wandering. While our work has concentrated on the use of patterns (Martino-Salzman et al., 1991) as an organizer, there are other typologies which remain untested, for example, those developed by Hussian and Davis (1985) and Hope et al. (1994). The further testing and refining of mechanical measures, within a variety of typologies, would assist in moving us closer to understanding how best to quantify the phenomenon.

Studies of wandering tend to utilize small samples. While this issue relates to difficulties in the recruitment of aged subjects generally, and the frail elderly with dementia specifically, the result is that the overall pool of subjects about whom we have information remains small. The protocols for subject selection have tended to be loose, meaning that subject comparison across studies is limited and generalization is difficult, if not impossible. Refinement of protocols for subject selection using more sophisticated medical diagnosis parameters and neuropsychological testing, for example, the NINCDS-ADRDA (McKhann et al., 1984) for AD or for MID would result in more homogenous samples about which more robust generalizations could be made than those currently possible. Studies with larger and random samples will also facilitate breakdown of data into diagnostic groups.

To date we have few data describing the stability and normal variation for any parameter of wandering over time. Thus, studies incorporating baseline and repeated measures would assist in future methodological decision-making. In studies designed to evaluate episode frequency or time in motion, it is critical that both the period of intervention is in effect, as well as the distribution of wandering over the rest of a 24 hour period is determined. In other words, did the intervention change the volume or the distribution of wandering? Without such clarity, the overall utility of interventions cannot be meaningfully interpreted in terms of clinical management.

7.17.9.2 Etiologic Factors

Research to date has proffered multiple explanatory hypotheses and employed a wide variety of research paradigms, none of which adequately explain the phenomenon. Thus, there is a need for well-controlled studies to test competing hypotheses or to evaluate the relative contribution of various putative etiologies for explaining wandering. While a number of potential etiologies have been suggested, measurement poses a problem in evaluating some of these in persons with severe dementia. For example, while proxy measures of circadian rhythm disturbance such as sleep and body temperature are reasonable, it is not directly possible to measure the function of the suprachiasmatic nucleus given current technology. Further exploration of the role of previous personality in disturbing behaviors associated with dementia is indicated, as demonstrated by the results of research utilizing the NEO five-factor personality inventory (Kolanowski, Strand, & Whall, 1997; Thomas, 1997). If, as suggested, the basic features of an individual's personality are preserved predominantly intact in AD, patterns of motor activity integral to the expression of personality may also be preserved.

While a number of proximal factors thought to be associated with wandering have been proposed in the NDB model (Algase et al., 1996), the extent of the impact of individual and amalgamated proximal factors in either moderating or exacerbating wandering is not known. Likewise, the conditions under which wandering can be altered have not been elucidated as yet. A number of studies have recognized wandering as influenced by a variety of environmental factors, yet studies that link type and amount of wandering to particular outcomes are few. Studies that use a theoretical perspective to isolate and manipulate individual or conceptually-grouped environmental factors are needed.

Looking more broadly in relation to other or related behavioral issues in dementia, an overlap and lack of clarity persists in current understandings of restlessness, agitation, wandering, and confusion. Initial concept clarification, followed by further development, testing, and refinement of measures for each concept in a severely impaired population is necessary. Existing measures for agitation, for example, do not adequately capture the frequency and intensity of the behavior in many wanderers. Likewise, measures for evaluating physiological need states such as thirst, hunger, fatigue, and elimination in the cognitively impaired require development.

Few tests for assessing areas of specific cognitive deficits in individuals with severe impairments have been developed and most are quite dependent on language skills. The results of such testing, especially in combination with neuroimaging and behavioral measures, may prove invaluable in further understanding the nature and origin of intellectual deficits and the impact of specific deficits on wandering. In studies that have attempted to examine specific aspects of cognitive function in relation to wandering, such as by Liu et al. (1991), most testing was done in grasping space (space within one's reach). Yet we do not know how tests of visual-spatial ability done in grasping space correspond with actual functioning in large-scale space.

7.17.9.3 Intervention Studies

While the clinical need for such studies is appreciated, the majority of intervention studies designed to impact wandering behavior are both premature and atheoretical. It is unclear in many studies what dimension of wandering the researcher is trying to manipulate. In many studies, wandering is only one of multiple behaviors examined and is not the single dependent variable of interest. Wandering is considered in an homogenous cluster with other behaviors such as agitation and elopement. Focusing research specifically on the phenomenon of wandering isolates the behavior and assists in clarity of definition. Intervention studies would also be more useful if derived from theory or based on putative etiologies for wandering.

Case study designs are an underutilized strategy in wandering research. Case study research has the advantage of small sample size, a particular advantage when working with a fragile and difficult-to-recruit population. Case studies can yield rich and complex descriptive data. Those designs using multiple cases with theoretically-structured embedded experiments afford generalization to theoretical propositions based on replication logic (Yin, 1989). Such replication offers compelling support for the initial set of propositions and the observations for each case are considered independent, that is, the intervention for one case does not affect the intervention for the other cases. More systematic use of case studies to accomplish descriptive and explanatory work and to provide a preliminary test of interventions is recommended.

In addition, certain institutional level studies would also be useful to answer questions such as these: (i) Are there characteristics of social environments that affect wandering? (ii) Does a match between the personality of the wanderer and that of the staff impact the behavior? (iii) Do certain institutional policies or physical design elements actually induce or exacerbate wandering?

The relative risk of undesirable outcomes associated with specific aspects or parameters of wandering behavior requires exploration. Which kinds and amounts of wandering predict falls? Or elopements? Is there a threshold at which wandering escalates weight loss? While not exhaustive, answers to these questions and response to issues raised above will do much to advance our understanding of wandering and the development of rational, humane, and effective care for the afflicted.

7.17.10 SUMMARY

This chapter has aimed to present a comprehensive overview of the state of the science on wandering behavior and its implications for research and clinical practice. Review of definitions and typologies revealed a lack of standardization and few attempts of researchers to build on the work of others. Thus, knowledge is disjointed and the ability to interpret results and generalize findings is hampered. Although some estimates of prevalence and incidence have been reported, their value is questionable for the same reasons.

A profile of the cognitively impaired person who may be prone to wandering was derived from a summary of the characteristics of wanderers across a number of studies. In short, neither age, gender, nor medical basis for dementia appears to differentiate wanderers from other cognitively impaired persons. However, differences in the characteristics of wandering behavior among these subgroups is unknown. In general, wanderers have better mobility and worse cognitive impairment on global measures than nonwandering counterparts. Language and visual-spatial skills are particularly affected. Long-standing active behavior patterns and an outgoing personality may also characterize the wanderer.

In an effort to clarify and advance conceptualizations of wandering, the behavior was differentiated from its outcomes. The following putative outcomes were isolated: falls, elopements, weight loss, sleep disturbance and fatigue, improved physical stamina, and worsened social and cognitive skills.

Several possible etiologies for wandering were proposed and the evidence in support of each were summarized. Disturbances in visual-spatial ability and evidence of parietal lobe damage (particularly, the right parietal lobe, which is associated with spatial learning) were offered to support the hypothesis that wandering is a reflection of spatial disorientation. Hippocampal damage, perseveration, and neurotransmitter imbalances involving acetylcholine and dopamine were suggested as the basis for wandering characterized as increased movement. Deterioration of the suprachiasmatic nucleus and the fractured sleep and activity patterns that accompany it provided the rationale for viewing night-time wandering as a reflection of circadian rhythm disruption. While less evidence exists to support the roles of affect and needs in explaining wandering, they cannot be eliminated as etiologies based on existing knowledge.

Behavior mapping, counting and timing strategies, and activity monitoring devices were reviewed for their value in assessing wandering behavior. Multiple assessment techniques for related factors, such as sensory abilities, personal patterns and preferences, and physical discomfort, and for outcomes were discussed.

A range of tested and untested approaches to intervention were evaluated. Few proven and effective techniques were found. Exercise may mitigate night-time wandering, but further study is needed. The effectiveness of cueing and lighting have not been demonstrated. Social interaction approaches are promising, but also require further study before specific protocols can be advocated. Drug therapy is the mainstay of treatment, but effects are global rather than specifically targeted to wandering and multiple issues can arise with the use of medications.

Techniques for managing the elopement attempts were also reviewed. Behavior modification can be effective if conditioned stimuli are continuously applied. However, replication and further evaluation of useful protocols is needed. Two types of camouflage have been evaluated for reducing exit attempts. Results are conflicting, but approaches based on visual agnosia may prove effective if strategies to overcome learning effects are incorporated. A range of perimeter control devices was also discussed but lack of data prevents development of clear recommendations at this time. Several additional strategies such as wandering paths and tracks, activities programming, and use of restraints (both physical and chemical) were also considered. While they are popular in clinical settings, their efficacy and value are unsubstantiated.

Finally, suggestions for further research were offered in the areas of definition and measurement, explanation, and intervention.

ACKNOWLEDGMENTS

The author is grateful for the assistance of Elizabeth R. A. Beattie, Ph.D., Senior Lecturer at James Cook University, Queensland, Australia, for her assistance in the initial draft of sections on assessment and intervention.

7.18.1 INTRODUCTION

7.18.1.1 Agitated and Aggressive Behavior

Among the behavioral disturbances experienced by older adults with cognitive impairment, agitation and aggression present the most serious consequences for both patients and their caregivers. These behaviors increase the likelihood of an individual being institutionalized (Moak & Fisher, 1990) and experiencing physical or chemical restraint (Sloane, Mathew, & Scarborough, 1991). Numerous reports from studies of family and professional caregivers indicate that aggression in cognitively impaired individuals is the most stressful problem that caregivers confront (Fisher, Fink, & Loomis, 1993).

Within institutional settings physical and chemical restraints have historically been among the most common forms of managing aggression and agitated behaviors (Evans & Strumpf, 1989; Swearer, Drachman, O'Donnell, & Mitchell, 1988). Reliance on these intervention strategies with Alzheimer's disease (AD) patients is wrought with problems due to side effects such as increased risk of falls (Werner, Cohen-Mansfield, Braun, & Marx, 1989), concomitant reduction of desirable behaviors, and the risk of impairment in cognitive functions. Several of the medications commonly prescribed for the treatment of agitation and aggression are psychotropic drugs developed for problems quite different from those experienced by the cognitively impaired elderly. While medications such as haloperidol may be effective in reducing agitated and aggressive behavior they can also have undesirable effects on other behaviors. In addition, as an older adult's physiology changes due to normal (e.g., metabolism rate) or pathological processes (e.g., Alzheimer's disease, hypertension) the effects of medication may be altered. The etiology of the behavioral disturbances themselves may also change, and therefore they may not be responsive to formerly effective interventions.

While the use of physical and chemical restraints may decrease or temporarily eliminate agitation, it is becoming increasingly apparent that restraint-based interventions are not likely to lead to long-term alleviation of behavioral disturbances, and the risks involved in their use often outweigh the benefits.

Interest in the development of restraint-free alternatives for managing behavior problems has been prompted by US Federal legislation affecting nursing home care. In 1987 the US Congress passed the Omnibus Reconciliation Act of Nursing Home Reform (OBRA) requiring that facilities receiving Medicare or Medicaid funds adhere to a treatment program requiring psychotropic drug holidays and the implementation of behavioral programming in an effort to reduce reliance on psychotropic medication within nursing homes. While the essence of OBRA represents a commendable improvement in the care of the elderly within institutions, the requirements for alternative interventions were implemented prior to the development and empirical validation of such treatment alternatives.

Despite the obvious need for alternatives to physical and chemical restraints, and the increase in research addressing behavioral disturbances, there are still remarkably few established treatment alternatives. Three factors have hindered the development of alternative interventions. First, the study of behavioral disturbances in dementia patients has historically occurred within a medical model. The vast majority of studies on behavior problems in cognitively impaired older adults are pharmacological studies. Research on the environmental context of behavioral functioning in dementia has only emerged since the 1980s. Second, there is a lack of consensus within the field regarding basic issues of definition. This lack of consensus has impeded advances in explanation, prevention, and treatment of these problems, and limits comparison of findings across studies. Third, the large majority of nonmedical studies of aggression and agitation are descriptive accounts that have been conducted in an atheoretical context. Most research reports do not reference or employ any theoretical framework within which to consider findings. The atheoretical nature of the research has limited advances in the explanation, prediction, and treatment of behavioral disturbances in the elderly.

The development of restraint-free methods for managing behavioral disturbances in cognitively impaired older adults entails questions regarding the extent to which behavior continues to be influenced by environmental stimuli. Given the limited predictive validity of available classification systems of dementia, it is believed that answers to these questions will be found most effectively through idiographically based assessment and treatment planning methods.

This chapter describes a theoretical approach to the assessment and treatment of behavioral disturbances that considers the context in which behavioral disturbances occur, including physiological and environmental setting events, antecedent environmental stimuli, and the consequences of the behavior. Information on the epidemiology, etiology, assessment, and treatment of agitation and aggression in the elderly is reviewed. A discussion of definitional issues is presented first.

7.18.2 ISSUES OF DEFINITION

A requisite condition of efforts to explain, predict, and modify behavior is the reliable measurement of key elements of the behavior. The operationalization of a target behavior is a critical first step in progress toward reliable, consistent measurement (Johnston & Pennypacker, 1980). A difficulty in formulating an adequate definition of agitation or aggression involves addressing the multidimensional nature of these behaviors and the dynamic nature of the interaction between physiological functioning and response to environmental stimuli inherent in a degenerative disorder such as Alzheimer's disease. Selection of the relevant dimension depends upon the ultimate goal of a measurement or assessment process. Definitions of behavioral disturbances may be based on etiology, topographical features, natural history, environmental dependence, impact on others, or treatment response. Intra- and interindividual variation in these dimensions has been a consistent finding in the literature despite efforts to identify common elements associated with behavioral disturbance in older adults grouped on the basis of factors such as diagnosis, level of cognitive impairment or functional skill impairment, or duration of illness. Within individuals with degenerative forms of dementia, variation in the etiology, environmental dependence, and response to treatment of topographically similar behaviors may change over time, further complicating the reliable identification of agitated of aggressive behaviors.

Any definition of agitation or aggression must be evaluated on the basis of reliable measurement of the behavior as operationalized and the accumulation of evidence for criterion-related concurrent and predictive validity and ultimately construct validity. Despite difficulties inherent in identifying the dimensions relevant for reliable and valid definitions of behavior in dementia, it is evident that attention to this issue is mandated to facilitate advances in the field.

In defining agitation and aggression, researchers have proposed both molar definitions that represent broad inclusive categories and highly specific descriptions of behaviors that are accessible to direct observation. Molar definitions typically require higher inference judgements (Foster & Cone, 1986). The utility of a particular definition will be influenced by the population to which it is applied. This is due to the significant heterogeneity of the population characterized by the label "elderly."

Perhaps the most widely cited molar definition of agitation was proposed by Cohen-Mansfield and Billig (1986). Agitation was defined as "inappropriate verbal, vocal, or motor activity that is not explained by needs or confusion per se" (p. 712). The authors' statement that agitated behaviors are always inappropriate with regard to accepted social norms or the needs of the caregiver reflects the fact that this definition was developed for the general population of elderly. There are at least two problems with this definition of agitation when applied to dementia patients. First, applying the concept of "inappropriate" behavior to dementia patients may itself be inappropriate as it implies that the behavior is unsuitable or incompatible in a given context. When the behavior of dementia patients is considered within the context of a patient's declining competencies and, hence, an increasingly challenging environment, it can be argued that their behavior actually is adaptive rather than inappropriate. Second, when the concept of social norms is applied to dementia patients, agitation emerges as the norm, thus making the normative reference within this definition unsuitable for the population of cognitively impaired older adults.

Other authors have proposed molar definitions that incorporate reference to the motivation of agitation. Barnes and Raskind (1980) defined agitation as a behavioral term addressing excessive motor activity that is often nonpurposeful in nature and is commonly associated with feelings of internal tension, irritability, hostility, and belligerency on the part of the individual engaging in the behaviors. Other definitions of agitation incorporate reference to the *consequences* of behavior. Rosen, et al. (1994), for example, defined agitation as consisting of vocal or motor behavior that is disruptive, unsafe, or interferes with the delivery of care in a particular environment. When treatment outcome is a primary concern, measures which incorporate the consequences of a particular behavior for patients and caregivers may be particularly useful.

A limitation of molar definitions is that the higher-inference judgments required can result in reduced reliability. Two approaches have been employed in attempting to increase the specificity of the definitions of "agitation" and "aggression." First, some researchers have focused on the frequency, duration, and intensity of discrete behaviors that are accessible to direct observation (e.g., Yudofsky, Silver, Jackson, & Endicott, 1986). Other researchers have provided lists specifying which behaviors are encompassed by the larger class of "agitation," and have grouped behaviors into various categories based on characteristics such as response modality (e.g., motoric vs. vocal) or dangerousness. For example, Rosen et al. (1994) described four behavioral classifications of agitation: (i) aberrant vocalizations (repetitious requests or complaints, and nonverbal vocalizations); (ii) motor agitation (pacing and wandering); (iii) aggressiveness (verbal or physical threats, harm to self or others, and physical behavior toward property); and (iv) resisting care (not taking medications or not cooperating with activities of daily living). Another example of a categorical approach to agitated behaviors is found in a study by Cohen-Mansfield (1986). Cohen-Mansfield included pacing, aimless wandering, inappropriate dressing or undressing, spitting, hitting, kicking, throwing things, screaming or making strange noises, biting, complaining, harming self or others, cursing, verbal aggression, constant unwarranted requests or statements, and general restlessness within the class of "agitated behaviors." A factor analysis produced three factors that have since been repeatedly cited as general forms of agitation and have been used to classify and study various aspects of agitation. The first factor is described as physically aggressive behavior, including spitting, biting, hitting, and throwing objects. The second factor includes verbal aggressive behavior such as cursing, threats, and verbal aggression. The third factor is described as nonaggressive behavior, including pacing, wandering, inappropriately dressing or undressing, and constant requests for attention.

Factor analytic methods of studying agitation and aggression may prove useful for understanding the etiology, natural history, or response to treatment of agitated or aggressive behavior. It is possible that behaviors associated with the various factors may emerge as having a similar etiology or response to treatment. Identifying behaviors that are functionally related will ultimately be the most effective for treatment development.

The difficulties inherent in defining agitated behaviors have had important implications for several areas of research, including epidemiological research.

7.18.3 PREVALENCE

Reports of prevalence rates of behavioral disturbances vary widely, depending upon the definition of agitated behavior used (e.g., summary terms such as "agitation" or "aggression" vs. specific behaviors such as screaming or hitting), the research methodology employed (e.g., caregiver report vs. direct observation), and characteristics of the population studied (e.g., nursing home residents vs. Alzheimer's disease patients). Prevalence rates of agitated behaviors also vary depending on whether the behavior is perceived to be a problem by others (Deutsch & Rovner, 1991). The following discussion of prevalence rates should be interpreted in light of these issues.

In a study of 408 residents in a large suburban nursing home, 93% of the residents were found to exhibit one or more of 29 agitated behaviors at least once a week as reported by caregivers using the Cohen-Mansfield Agitation Inventory (CMAI) (Cohen-Mansfield, 1986; Cohen-Mansfield, Marx, & Rosenthal, 1989). Participants in this study were identified as having various levels of cognitive impairment and physical limitations. General restlessness was the most commonly manifested behavior. Other high-frequency behaviors included pacing, repetitious sentences, constant requests for attention, complaining, negativism, and cursing. Physically nonaggressive behavior and verbally agitated behaviors were considerably more common than aggressive behaviors. In general, the frequency of agitated behaviors decreased throughout the day as the evening approached, and occurred least frequently at night when the majority of residents were sleeping. In contrast, a study by Teri, Larson, and Reifler (1988) reported that 26% of the total sample of 127 individuals with Alzheimer's disease exhibited agitation. Participants in this study were outpatients referred to a geriatric and family services clinic for a comprehensive geriatric evaluation. "Agitation" was considered separately from "wandering" and "restlessness." Levels of agitation varied with level of cognitive impairment as assessed with the Folstein Mini-Mental State Exam (MMSE; Folstein, Folstein, & McHugh 1975). Behavior problems were rated as present or not present by a physician based on observations or information provided by family of the participants. Ten percent of individuals with mild, 27% of those with moderate, and 38% of those with severe, cognitive impairment were identified as exhibiting agitation. Wandering and restlessness were evidenced in 26% and 45% of the entire sample, respectively.

7.18.4 ETIOLOGICAL FACTORS

Several factors have been proposed to contribute to the development of agitation and aggression in older adults. These factors include medication (Addonizio, 1987), illness such as infection (Yoshikawa & Norman, 1996), cognitive impairment (Cooper, Mungas, & Weiler, 1990), functional status (Cohen-Mansfield & Billig, 1986), environmental stimuli (Burgio et al., 1994; Cohen-Mansfield, Werner, & Marx, 1992; Fisher, Goy, Swingen, & Szymanski, 1994) and emotional states (Swearer, et al., 1988).

Based on the large variation in the physical and psychological functioning of older adults, the following guidelines may be useful for generating hypotheses regarding antecedent or etiological factors contributing to agitation or aggression in an older adult: (i) Given the significant variation in the health and cognitive status of older adults, identification of the etiology of aggression and agitation is best considered within an interactional model that includes physiological, psychological, and environmental factors; (ii) While an individual may exhibit topographically similar behaviors at different points in time, it should not be assumed that the same factors that contributed to the behavioral disturbance in the past are causing the current problem. Variation in etiology is a particularly salient issue when an individual has a degenerative condition such as Alzheimer's disease, in that topographically similar behaviors may have different etiologies over the course of the disease. Physiological and psychological factors that have been found to be associated with agitation and aggression in older adults are reviewed.

7.18.4.1 Physiological Factors

Physiological factors contributing to agitation and aggression can be conceptualized as falling into two categories: (i) direct precipitants of; or (ii) setting events for agitation or aggression. The term "setting events" refers to conditions of the individual or the environment in which the individual functions that affect the function of the antecedent or consequent stimuli associated with a particular response (Bijou & Baer, 1966; Kantor, 1959). Physiologically based setting events that may increase the risk of agitation or an aggressive response include patient fatigue, hunger, mood, health status, cognitive impairment, and sensory functioning. The categories of physiological factors described below may serve as a guide for generating hypotheses regarding factors influencing aggression or agitation in older adults.

Physiological conditions that have been identified as predisposing patients to become agitated or to behave aggressively include pain, physical discomfort, and sensory impairment. Evidence for their role in the etiology of agitation and aggression will be reviewed.

7.18.4.1.1 Pain

There are several painful physical conditions that may influence the occurrence of agitation and aggression. Infectious processes (Gerdner & Buckwalter, 1994), such as urinary tract infection, may produce pain in a cognitively impaired patient and may go undetected because of the inability of the patient to verbally express discomfort. Other sources of pain, such as heartburn, sinus congestion, arthritis, neuropathy from diabetes, or injury (e.g., stress fracture), may lead to agitation (Ferrell, Ferrell, & Rivera, 1995) or function as setting events in that they increase the likelihood of agitation or aggression occurring when stress is placed on the patient (e.g., when environmental stimulation is high or demands are placed on the patient in the context of caregiving).

7.18.4.1.2 Medication

Due to age-associated decreases in metabolism, older adults are at increased risk for iatrogenic effects associated with drug toxicity, drug interactions, and drug withdrawal (Gerdner & Buckwalter, 1994). Problems associated with polypharmacy have received extensive attention in the geriatrics literature for several years (Buck, 1988; Ray, Federspiel, & Schaffner, 1980; Williams & Betley, 1995). Surveys indicate that both psychotropic and nonpsychotropic medications continue to be widely over prescribed for older adults in nursing homes (Williams & Betley, 1995) and board and care homes (Spore, Mor, Hiris, Larrat, & Hawes, 1995). While polypharmacy often plays an important role in treatment of older adults, with increased numbers of medications, the risk of one medication negating, potentiating, or in some way altering the effects of another medication increases. Medications with side effects that may contribute to agitation in an elderly individual include but are not limited to neuroleptics (Addonizio, 1987), benzodiazapines (Wolf, Grohmann, Beiber, Brenner, & Luther, 1989) and nonprescription medication with anticholinergic properties (Hall, Beresford, Stickney, Nasdahl, & Coleman, 1985; see Callahan, 1993 for a review).

7.18.4.1.3 Sensory and perceptual deficits

Visual and hearing impairments may contribute to the occurrence of agitation and aggression in that they may produce or increase confusion and alter perception of the dangerousness of a situation. Perceptual impairments such as visual neglect due to stroke may also contribute to violent behavior.

7.18.4.2 Psychological Factors

7.18.4.2.1 Cognitive factors

The relationship between cognitive functioning and behavioral disturbance has received the largest amount of attention by researchers attempting to determine the cause of behavioral disturbance. Studies have examined the relationship between the number and/or types of behavioral disturbance and either cognitive status as measured by neuropsychological test performance and/or functional/adaptive skill level as measured by behavioral checklists. The results have varied. Some studies have reported a positive correlation (Cooper et al., 1990) while other researchers have found no relationship (Bolger & Dougherty, 1992; Teri, Borson, Kiyak, & Yamagishi, 1989) or a nonlinear relationship (Cohen-Mansfield, Marx, & Rosenthal, 1990) between overall number of behavior problems and cognitive status. Studies that have found a statistically significant relationship between cognitive status and behavioral disturbance have reported relatively low correlations accounting for little of the variance (e.g., Cooper et al., 1990).

In a study of Alzheimer's disease patients residing in a nursing home, Teri et al. (1988) found that the number of behavioral problems was positively correlated with cognitive impairment. The types of behavior problems manifested varied with the level of cognitive impairment. Wandering, agitation, and incontinence were found to be most heavily associated with level of cognitive impairment.

In a related study designed to further clarify the relationship between behavioral problems and level of cognitive and functional impairment in 56 moderately impaired Alzheimer's disease patients, Teri et al. (1989) found that the problems most strongly associated with level of cognitive functioning were confusion, disorientation, and memory loss. These problems constituted at least 50% of the total for problems that occurred more than twice per week as recorded by caregivers using the Behavioral Problems Checklist (BPC). The next most common problems were underactivity, loss of interest in activities, tension, depression, and apathy. No caregiver reported an absence of problems for an individual patient, and an average of seven of the 48 problems on the BPC were reported to have occurred more than twice per week. This study also identified gender differences in problem behaviors, as men were found to have significantly higher rates of the following problems: preoccupation with bodily functioning, loss of interest in activities, verbal aggression towards others, loss of interest in others, and poor personal hygiene. Perhaps the most important finding to emerge from this study is that no specific behavioral problem or pattern of behavior problems was associated with overall level of cognitive impairment.

7.18.4.2.2 Environmental factors

Research provides compelling evidence for the role of environmental influence on behavior in even very severely cognitively impaired older adults (Bourgeois, Burgio, & Schulz, 1995; Burgio et al., 1994; Vitaliano, Young, Russo, Romano, & Magana-Amato, 1993). Findings from observational research have been particularly informative in describing the influence of environmental factors on the occurrence of agitation and aggressive behavior (Anderson, 1970; Colenda & Hamer, 1991; Hamel et al., 1990; Vitaliano et al., 1993). Lindsley (1964) delineated four components for the functional analysis of behavior that can be applied to the behavior of dementia patients. These include (i) the antecedent stimulus or stimulus setting in which the behavior occurs, (ii) the behavior of interest (e.g., aggression or agitation), (iii) the contingencies of reinforcement, and (iv) the environmental events that follow the behavior. To this list others have added the concept of "setting events" (Kantor, 1959) which are conditions of the individual or the environment that affect the function of antecedent and consequent events.

(i) Setting events

Environmentally based setting events may include factors such as noise level, the presence of others, or a change in caregiver that affects the function of antecedent or consequent stimuli associated with agitation or aggression. Variation in the occurrence or intensity of aggression or agitation when the antecedent stimuli (e.g., caregiver's behavior) appear constant, may be associated with a change in environmental setting events (see Carr, Levin, McConnachie, Carlson, Kemp, & Smith, 1994). Time of day may also function as a setting event in that it has been shown that the frequency of aggressive acts decreased from day to evening to night (Cohen-Mansfield et al., 1989). Using the Cohen-Mansfield Agitation Inventory as a measure of agitated behaviors in 408 nursing home residents with varying degrees of physical and cognitive impairment, Cohen-Mansfield et al.

(1989) reported that the majority of behaviors occurred at significantly different rates across day, evening, and night shifts with frequency decreasing from day to evening to night. There are at least three possible explanations for this finding. First, patients may become increasingly fatigued as the day progresses, and therefore the decrease in agitated behaviors is a function of energy level. Second, the administration of medications and/or the application of physical restraints may decrease or preclude a patient's ability to engage in agitated or aggressive behaviors. Or third, the environment within the nursing homes changes across the day (e.g., due to changes in the caregiving or activity schedules). In short, the finding may reflect changes in environmental setting events (e.g., activities in the nursing home) or physiological setting events (e.g., fatigue or the use of medications).

The role of emotion as a setting event associated with agitation and aggression has been receiving increasing empirical attention. Research suggests that a patient's emotional state, such as level of anxiety or depression (Swearer et al., 1988) may be predictive of agitation and aggression. In a 1996 study Lawton, Van Haitsma, and Klapper (1996) reported that AD patients who were rated as "less content" were also considered more agitated by staff members. Swearer et al. (1988) found that 63% of caregivers reported that the patient for whom they provided care exhibited one or more symptoms of anxiety, including general fearfulness, a fear of specific objects or events, restlessness, pacing, and appearing to worry over insignificant matters and that these behavioral symptoms of anxiety tended to be significantly associated with angry outbursts

In a rare investigation of the association of premorbid history and agitation in nursing home residents, Cohen-Mansfield and Marx (1989) found that residents who experienced a major stressful event during their lives tended to exhibit a greater number of agitated behaviors—in particular, physically nonaggressive behavior. Residents who had not experienced relocation prior to being admitted to the nursing home exhibited more aggressive behavior and a greater number of agitated behaviors than did residents who had relocated at least once. The results of this study suggest that exposure to stressful events earlier in life may result in the development of coping skills or an increase in the threshold for perceiving events as stressful in later life. The changes produced by exposure to stress earlier in life may continue to influence behavior after the onset of a dementing process.

(ii) Antecedent stimuli

Several studies have reported that antecedent environmental stimuli such as task demands influence the occurrence of agitation and aggression. The finding of an association between environmental stimulation or caregiver demands and behavioral disturbance in cognitively impaired elderly indicates that these behaviors are not random or purposeless but instead may be functionally related to environmental stimuli.

Attempting to engage patients in activities of daily living, including being bathed, changed, or fed, has been described by nursing home staff as a primary cause of agitation (Cohen-Mansfield, 1986). These findings are consistent with those of Fisher et al. (1994) that aggressive behavior in Alzheimer's disease patients was consistently associated with a nurse's request to perform a task. In a study of 42 institutionalized dementia patients, Fisher et al. (1994) found that nurses described all physically assaultive AD patients as appearing distressed during episodes of aggressive behavior. For 80% of these patients, physically aggressive behaviors were described as being associated with an effort to escape from a stimulus, such as a nurse's request.

The concept of a "catastrophic reaction" (Goldstein, 1952) is frequently mentioned within the context of efforts to account for aggressive outbursts in dementia patients (e.g., Hall, Gerdner, Zwygart-Stuffacher, & Buckwalter, 1995). A "catastrophic reaction" occurs when demands presented by the environment exceed the patient's ability to cope. The individual becomes increasingly anxious and may attempt to terminate the anxiety-provoking stimulus by expressing a desire to be alone, screaming, or asking to go home. Continued stimulation may result in the individuals becoming extremely agitated or violent. The reports that aggression is often associated with an effort to escape from an aversive situation, described above, are consistent with the concept of catastrophic reaction.

The presence of other people has also been shown to be associated with agitation (Ryden, 1988; Cohen-Mansfield, Werner, & Marx, 1992). In a study involving 24 dementia patients described as highly agitated on the basis of CMAI scores, Cohen-Mansfield, Werner, and Marx (1992) reported that the agitated behaviors of pacing, strange noises, requests for attention, strange movements, aggressive behaviors, picking at things, and repetitious mannerisms were differentially affected by the presence of others. For example, strange noises were shown to increase when the patient was left alone while pacing decreased in the same situation.

Other environmental stimuli reported to influence behavioral disturbances include the caregiver's emotional expression (Vitaliano et al., 1993), lack of structure, and lack of attention (Cohen-Mansfield, 1986).

These findings support the hypothesis that certain behaviors that emerge during the course of dementia may serve a function for dementia patients in that they may be an adaptive (and the only available) means of increasing or decreasing stimulation. As a patient's behavioral repertoire diminishes over the course of a dementing process, behaviors characterized as "agitated" or "disturbances" may emerge to serve the function of previously available behaviors (e.g., those associated with language, leisure activities, or social interaction).

(iii) Environmental consequences

The consequences of agitated behaviors and aggression have received the least amount of attention by researchers. Little is known regarding how caregiver behavior following aggression functions to maintain or reduce aggression. Several possible relationships between behavior and consequences may be relevant. Aggressive behavior may be influenced by positive reinforcement if the former's occurrence is associated with the presentation of a consequent stimulus (e.g., caregiver attention) that increases the probability of the behavior occurring in the future. Alternatively, negative reinforcement may serve to strengthen aggressive tendencies through the contingent removal of an aversive stimulus (e.g., task demand). A few case studies (e.g., Bakke et al., 1994) discussed in detail in the intervention section, have described functional relationships between agitated behavior and environmental consequences.

(a) Social consequences. Aggression associated with positive reinforcement in the form of attention appears to be rare in dementia patients, although a few case reports have described an association between agitation and social contact (e.g., Rosberger & MacLean, 1983). When social contact is implicated in an aggressive episode, it is more often associated with an effort to terminate social contact (Fisher, 1995).

(b) Tangible consequences. Aggressive behaviors exhibited by cognitively impaired older adults may be associated with an effort to gain a tangible consequence such as food or an object. The role of tangible consequences in the development and maintenance of aggression within community settings has not been explored. Within institutional settings such as nursing homes, access to tangible objects is limited for safety purposes. The most frequent type of tangible consequence for a behavior that appears aggressive involves obtaining food from another resident (e.g., grabbing food from another resident) (Fisher et al., 1994).

In another scenario, a patient may grab onto or pinch the caregiver in a painful fashion during caregiving tasks. While the behavior may appear aggressive in that it causes pain for the caregiver, it may function to provide security or stimulation. Identifying an alternative response that is incompatible with the seemingly aggressive one, such as placing an object (e.g., a towel or small pillow) in the patient's hand prior to initiating the caregiving activity may prevent this form of aggression (Lundervold & Lewin, 1992).

7.18.5 ASSESSMENT

Interest in the assessment of behavioral disturbances in AD has increased since the mid-1980s. However, there are several limitations to our understanding of agitation and aggression and the reliability and validity of assessment procedures. First, there is a lack of consensus in the field regarding the definitions of agitation and aggression. Second, as discussed earlier in this chapter, the majority of available assessment instruments focus on the topographical features of agitation and aggression and have limited utility for treatment planning. Third, few of the available instruments have been validated for use with dementia patients. Psychometric studies have focused primarily on the reliability of instruments. The predictive validity and treatment utility of the majority of instruments have not been empirically evaluated.

The physiological, topographical, and functional characteristics of agitation and aggression in cognitively impaired older adults and the significance of each of these areas in assessment and treatment planning are explored in the following sections.

7.18.5.1 Physiological Assessment of Agitation and Aggression

For the purposes of determination of etiology and treatment planning, assessment of agitation should begin at the physiological level. Assessing and treating physical symptoms contributing to agitated behavior may eliminate the need for the more time-consuming assessment of environmental causes of agitation. While there have been few empirical investigation regarding the physiological correlates of agitation in dementia patients, pain and sensory impairment have been implicated in the etiology of agitation and is reviewed.

7.18.5.1.1 Pain

A particularly difficult challenge in caring for cognitively impaired individuals involves their limited verbal abilities. As verbal abilities decline, caregivers must increasingly rely on observation to determine whether a patient is experiencing pain or distress. It is crucial for adequate treatment planning to rule out physical pain as a precipitant to aggression. Regular physical examinations are a necessary component of adequate care.

Although assessment of pain is complicated by the impaired verbal abilities of the dementia patients, Ferrell et al. (1995) reported that 83% of a sample of 217 cognitively impaired dementia patients was able to complete at least one of the five unidimensional measures used to assess pain. The unidimensional measures used included: (i) a verbally administered questionnaire in which subjects were asked to choose among descriptors of pain listed in one-inch letters on large index cards (McGill Pain Questionnaire; Melzack, 1975); (ii) a verbally administered 0–10 Likert scale; (iii) a 100 mm visual analog scale with word anchors of "no pain" and "worst possible pain" (p. 593); (iv) a subscale of the Memorial Pain Card (Fishman et al., 1987) involving the visual and verbal presentation of eight words describing various intensities of pain ranging from no pain to excruciating; and (v) the Rand Coop Chart for pain (Nelson et al., 1987) that requires subjects to choose one of five cartoon characters accompanied by descriptive words depicting various levels of pain, ranging from no pain to severe pain.

Ferrell et al. (1995) report that 62% of subjects who were able to complete the assessment reported the presence of pain and 40% of the sample reported pain in more than one location. Further, for 37% of patients who reported pain, no etiology for the described pain was documented in the medical records. These findings indicate the high prevalence or pain among dementia patients.

While Ferrell et al. (1995) indicate that this study provides support for the ability of cognitively impaired dementia patients to report pain, several factors may limit the generalizability of the findings to moderately and severely impaired patients. First, the authors did not report the reasons why 17% of the sample was unable to complete the interview. The inability of a significant subset of the sample to complete the interview suggests that the results may not be generalizable to more impaired patients. Second, it is unclear whether the discrepancy between subject reports and medical records reflects inaccurate reporting by the dementia patients or insufficient documentation in patient charts. Research indicates that while interviewing is a helpful assessment tool with mildly impaired individuals, it is not effective as cognitive decline progresses (Davis & Robins, 1989). The limited utility of interviews with dementia patients is reflected by the elimination of 70 subjects prior to selection of the final sample in the Ferrell et al. study. The authors report that these subjects were eliminated, because they were "essentially mute and unresponsive, and no meaningful information could be obtained from the patient interview" (p. 594). The omission of severely impaired patients reflects the difficulty in clarifying the relationship between pain and agitation or aggression in dementia patients, since these behaviors are generally more likely to appear when cognitive impairment is moderate to severe (Kurita, Blass, Nolan, Black, & Thaler, 1993; Swearer et al., 1988).

Given the limitations of the use of interviews for assessing pain in severely impaired AD patients, it is usually necessary to rely on direct observation methods. Hurley, Volcier, Hanrahan, Houde, and Volcier (1992) developed the Discomfort Scale for Dementia of the Alzheimer's type (DS-DAT) to assess discomfort in AD patients through direct observation of facial expressions and body posture. The authors defined discomfort as "a negative emotional and/or physical state subject to variation in magnitude in response to internal or environmental conditions" (p. 369). Behavioral signs of discomfort on the DS-DAT include noisy breathing; negative vocalization; having a frown; fidgeting; and looking sad, frightened, or tense.

The construct validity of the DS-DAT was evaluated by administering the scale monthly to AD patients who were highly dependent on the nursing staff for their activities of daily living. During the course of the study 20 subjects were identified as having an acute illness typically manifested by fever. It was hypothesized that discomfort would be higher during a fever episode than during baseline. The results indicated that the DS-DAT was sensitive to changes in discomfort associated with fever episodes. A limitation of this study is that the observers were not blind to the patients' fever episodes. While this knowledge may have biased observations, the results indicate that reliable, systematic observation of discomfort in AD patients is possible. Such observation may provide caregivers with information necessary to assist in assessment of physiological factors in the etiology of agitation.

While no studies, up to 1997, have directly assessed the relationship between pain and agitation, it is important to continue to explore this relationship. The promising developments in the assessment of pain in dementia patients described above, support the need to explore this venue. Reliable methods for assessing pain in the cognitively impaired individuals may help in the identification of physiological factors contributing to agitation and aggression and, hence, inform treatment.

7.18.5.1.2 Sensory impairment

Sensory impairment may also contribute to agitation (Gerdner & Buckwalter, 1994). Dementia patients, who are unable to correct for inadequacies in sensory perception by gathering more information or by altering their behavior (Fisher & Carstensen, 1990) may experience significant confusion and subsequent distress associated with sensory decrements.

Deficits in vision and hearing may contribute to a patient's inaccurate perception of situational demands. Patients with severe sensory impairment may overestimate the dangerousness of a situation and behave aggressively out of fear and a perceived need for self-defense. Assessing the status of a dementia patient's sensory functioning may provide information regarding how they perceive the environment and whether sensory deficits are contributing to a tendency toward agitation or aggression.

7.18.5.2 Topographical Assessment of Agitation and Aggression

The majority of research regarding the assessment of agitation and aggression has addressed the topographical features of the behaviors. Topographical assessment is informative for the identification of target behaviors and the frequency and intensity of these behaviors. Topographical information is also critical for assessment of baseline levels of aggressive or agitated behavior and for monitoring the effects of interventions. Four assessment instruments designed to record the frequency and intensity of agitation or aggression will be reviewed.

7.18.5.2.1 Cohen-Mansfield Agitation Inventory

The Cohen-Mansfield Agitation Inventory (CMAI; Cohen-Mansfield, 1986) is a 29-item questionnaire designed to measure the types and frequencies of agitated behaviors exhibited by elderly nursing home residents. Respondents rate the frequency on a seven-point scale ranging from "1—never engages in" to "7—manifests the behavior on the average of several times an hour." Examples of items include "pacing," "cursing or verbal aggression," and "repetitious sentences or questions." Cohen-Mansfield et al. (1989) reported adequate interrater agreement for each behavior on the CMAI (average $r = 0.92$). Studies of the reliability of the CMAI by other groups have produced varying levels of support for interrater reliability. Finkel, Lyons, & Anderson (1992) found evidence for high internal consistency but high variation in interrater reliability across items. In 1995, Miller, Snowdon, and Vaughan (1995) reported adequate interrater reliability for aggressive ($r = 0.85$) and physically nonaggressive behaviors ($r = 0.73$) but low interrater reliability for agitated verbal behaviors ($r = 0.47$).

7.18.5.2.2 Pittsburgh Agitation Scale

The Pittsburgh Agitation Scale (PAS; Rosen et al., 1994) is designed to assess four categories of agitated behavior in dementia patients, including aberrant vocalization, motor agitation, aggressiveness, and resisting care. Behaviors are rated using a five-point scale ranging from "0" indicating that the behavior was not observed during the specified observation period, to "4" indicating severe intensity, frequency, and/or resistance to redirection of the behavior. The authors report adequate intraclass correlations and concurrent validity based on findings from studies of dementia patients from an acute-care geropsychiatric unit and a chronic-care nursing facility.

7.18.5.2.3 Overt Aggression Scale

The Overt Aggression Scale (OAS; Yudofsky et al., 1986) is a checklist designed to document specific aspects of aggressive behavior based on observable criteria. It is designed to be completed immediately following each aggressive incident. In addition to indicating which of 16 behaviors occurred during an incident, raters also record the intervention strategies used and the time of onset and duration of the incident. The 16 behaviors on the OAS are divided into four categories: verbal aggression, physical aggression against objects, physical aggression against self, and physical aggression against others. Sample behavioral items include "Makes loud noise, shouts angrily," "Bangs head, hits fists into objects, throws self onto floor or into objects (hurts self without serious injury)," and "Slams doors, scatters clothing, makes a mess." Sample intervention items on the OAS include "Talking to patient," "Closer observation," and "Use of restraints." Silver and Yudofsky (1991) reported that the OAS captured 98% of aggressive incidents documented in medication books, hospital charts, and ward communication books combined, indicating adequate concurrent validity.

A limitation of the OAS is that it may be logistically difficult to complete the form for each incident of aggression when they occur at a high frequency (Ratey & Gutheil, 1991; Sorgi, Ratey, Knoedler, Markert, & Reichman, 1990). In an effort to eliminate this problem, Sorgi et al. (1990) developed the retrospective OAS using the original 16 items contained in the OAS, but with a modified scoring and temporal interval. The frequency of occurrence for each item is rated on a five-point Likert-type scale ranging from "0" to "greater than 10 times." The retrospective OAS is designed to reflect the patient's behavior over the previous week. The authors report adequate interrater reliability ($r = 0.96$) and internal consistency ($\alpha = 0.75$). Ratey and Gutheil (1991) also developed a modified version of the OAS to reduce respondent burden. However, they did not report information regarding its psychometric properties.

While empirical reports of the use of the OAS and the retrospective OAS with dementia patients have not emerged, given that the behaviors and interventions included on the OAS are observed in dementia patients, it is reasonable to assume that the instruments are appropriate for use with this population.

7.18.5.2.4 Blessed Dementia Scale

The Blessed Dementia Scale (BDS; Erkinjuntti, Hokkanen, Sulkava, & Palos 1988) is a 22-item scale that assesses cognitive functions, activities of daily living, instrumental activities of daily living, and personality characteristics. The BDS is administered within the context of interview with an informed respondent. Activities of daily living are rated on the basis of the frequency with which the client is able to perform the task (e.g., daily, occasional, always). Changes in personality, interests, and drive are rated as present or absent. Examples of items from the activities of daily living category include "Inability to perform household tasks" and "Inability to recall recent events." Personality items include "Increased egocentricity," "Impairment of emotional control," and "Sexual misdemeanor." The BDS has been shown to discriminate between institutionalized dementia patients and elderly community residents with no organic impairment.

7.18.5.3 Assessment of Functional/Contextual Features

Information regarding the frequency, duration, and intensity of agitation and aggression is necessary but insufficient for treatment planning. Research has consistently indicated that environmental factors influence behavioral disturbances in dementia patients, and therefore systematic identification of the environmental characteristics associated with agitation or aggression is essential for the determination of whether a behavior is environmentally dependent, and if it is, the features of the environment on which it is dependent. Specific factors that merit attention in the functional analysis of agitation include setting events, antecedent environmental stimuli, response characteristics, and response consequences.

7.18.5.3.1 Setting events

Setting events include, but are not limited to, factors such as patient mood, fatigue, level of cognitive impairment, physical status, or sensory functioning that affect the relationship between antecedent stimuli and consequences associated with aggression or agitation. A challenge in developing interventions for patients with a degenerative dementia is the inherently dynamic nature of the relationship between setting events and behavior as neuropathology progresses. An idiographic approach to assessment will be the most effective for addressing variation in the interaction between cognitive impairment, environmental stimuli, and behavior.

7.18.5.3.2 Antecedent environmental stimuli

Evidence for the importance of identifying antecedent stimuli associated with aggression and agitation has emerged from several studies that have documented a systematic relationship between the occurrence of these behaviors and various environmental stimuli (Cohen-Mansfield, Marx, Werner, 1992; Ryden, 1988). When, through repeated pairing of a stimulus and a particular reinforcement contingency, a stimulus comes to signal that reinforcement is available contingent on a particular response, the behavior is considered to be under stimulus control. The stimulus which signals that reinforcement is available contingent on a particular response is termed a discriminative stimulus.

Factors associated with the development and maintenance of the stimulus control of behavior in dementia patients have not be delineated. Idiographically based methods for determining whether a particular behavior exhibited by a dementia patient is under stimulus control are described below.

7.18.5.3.3 Response characteristics

In consideration of response characteristics, the topography of aggression and agitation in dementia patients has been the primary focus of empirical attention. Patients' emotional responses to environmental stimuli have not been systematically investigated. Cohen-Mansfield (1986) reported that lack of attention can be a precursor to agitation. It is possible that lack of attention leads to boredom, thus producing a functionally adaptive self-stimulatory behavior in dementia patients, such as stereotypic movement.

Another emotional response characteristic that may influence response to environmental stimuli and the subsequent occurrence of agitation or aggression is anxiety. Hall et al. (1995) suggested that AD patients may overestimate the dangerousness of a caregiver session, for example, as a result of confusion caused by cognitive impairment. Perceiving the environmental stimuli as dangerous may result in high levels of anxiety. Due to cognitive limitations the patient's repertoire of behaviors for coping with an anxiety-provoking stimulus is reduced (e.g., the patient is unable to verbalize a request to terminate the interaction), and the patient may strike the caregiver. The aggressive behavior may be negatively reinforced by termination of the caregiver's demands and subsequent reduction in the patient's anxiety. In this situation assessment of emotion as a response characteristic may suggest a proactive intervention such as presenting the patient with a distracting stimulus such as soothing music or a soft object to carry.

7.18.5.3.4 Environmental consequences

The consequences of agitation and aggression have received the least amount of attention by researchers. Little is known about how patient and caregiver behavior following behavioral disturbances function to maintain or reduce these behaviors. It is possible that termination of caregiver's demands or the reduction of an aversive emotional state may function to negatively reinforce agitated or aggressive behavior.

The instruments described below may be useful for formulating hypotheses regarding the functional context of agitated behaviors.

7.18.5.3.5 Motivation Assessment Scale

The Motivation Assessment Scale (MAS; Durrand & Crimmins, 1988) is a 16-item questionnaire designed to identify variables maintaining self-injurious behavior. It addresses four categories of situational determinants of self-injurious behavior including social attention, tangible consequences, escape from unpleasant situations, and sensory consequences. Respondents are asked to rate the likelihood of the specified target behaviors occurring in each of the situations listed using a seven-point Likert-type scale ranging from "0—never" to "6—always." Sample questions include, "Does this behavior occur repeatedly, over and over, in the same way?" and "Does this behavior occur when you are talking to other persons in the room?" The four categories on the MAS were supported by a factor analysis conducted by Bihm, Kienlen, Ness, and Poindexter (1991).

Durrand and Crimmins (1988) investigated the psychometric properties of the MAS on a sample of 50 developmentally disabled children. They found that the scale had adequate internal consistency, test–retest, and interrater reliability. The scale also demonstrated adequate concurrent validity. The reliability and validity of this scale for use with dementia patients have not been empirically investigated.

Subsequent studies on the interrater reliability of the MAS have produced varied results. Zarcone, Rodgers, Iwata, Rourke, and Dorsey (1991) applied the MAS to a population of subjects with severe disabilities using self-injurious behavior as the target behavior and reported interrater agreement ranging from -0.24 to 0.44. Sigafoos, Kerr, and Roberts (1994) also found low interrater reliability ($r = 0.03$) of the MAS when applied to subjects with profound intellectual disability and using aggressive behavior as targets. However, Kearney (1994) reported adequate interrater reliability ($r = 0.55$–0.79) when using the scale with a sample of mentally retarded adults and a variety of agitated behaviors (e.g., aggression, self-injury, screaming) as targets.

7.18.5.3.6 Behavior Environment Taxonomy of Agitation

The Behavior Environment Taxonomy of Agitation (BETA; Fisher, 1995) is a 16-item checklist that asks respondents to describe the likelihood of specific agitated behaviors occurring in any of four classes of situations. The BETA represents a modification of the MAS. A preliminary study of the utility of the MAS for use with AD patients, involving 17 AD patients, found that the category "tangible consequences" was ranked last (i.e., least relevant) for 58% of cases with a mean ranking of four out a possible five. Items associated with tangible consequences were endorsed as relevant almost exclusively for the behavior "Grabbing." This association was judged to be uninformative. Therefore, in an effort to reduce respondent burden associated with completing the BETA and to improve its utility, items pertaining to tangible consequences were eliminated. The situations described in the BETA have been identified in the literature (Anderson, 1970; Colenda & Hamer, 1991; Hamel et al., 1990) and by caregivers (Fisher et al., 1994) as being associated with the occurrence of agitation in dementia patients and in other clinical populations, including developmentally disabled persons and psychiatric patients (Durand & Crimmins, 1988; Paul & Lentz, 1977). The classes of situations on the BETA include: (i) social attention; (ii) escape from unpleasant situation; (iii) increase sensory consequences; and (iv) reduce sensory consequences Nurses and CNAs rate the likelihood of occurrence of four examples of each of these classes of situations on a seven-point Likert-type scale ranging from "0—never" to "6—always."

To evaluate the interrater reliability of the BETA, mean scores for the four BETA categories were ranked. The approach of ranking of category scores was used, because this approach is most consistent with how the categories are used clinically. The highest mean score was given a rank of one. The other mean scores were given ranks of two, three, and four, respectively. Tie ranks were averaged. Spearman rank-order correlation coefficients for the category scores indicated consistency in BETA ratings between respondents (median $r = 0.83$, $p < 0.01$). Test–retest reliability was evaluated using Spearman rank-order correlation coefficients for the category scores. Results indicated consistency in BETA ratings over time (two to three week interval) (median Spearman $r = 0.80$, $p < 0.01$).

Initial investigations regarding the factor structure of the BETA using a normalized varimax rotation factoring program revealed that the four factors that emerged are essentially equivalent to the subscales proposed in the revision of the BETA. The exceptions appear to be associated with the category "Reduce sensory stimulation." Items which include a reference to "stimulation" may load more heavily on a separate factor. This finding may also be associated with respondents' interpretation of the term "stimulation."

7.18.5.3.7 Functional Analysis of Behavior Recording and Tracking Forms

The Functional Analysis of Behavior (FAB; Lundervold and Lewin, 1992) is designed to assess the antecedents and consequences of verbal abuse and combativeness. It is divided into two parts each of which is completed when the target behavior occurs. Respondents record the date and time of each occurrence and place a checkmark next to the situation that immediately preceded the behavior. Examples of situations described on the form include "Meal time," "Bath time," "Dressing," and "Command." A brief description of the intervention that was implemented to address the behavior problem is also recorded.

The FAB Tracking Form (Lundervold & Lewin, 1992) is designed for monitoring the frequency with which several target behaviors occur and treatment progress. Respondents record (i) the type of behavior exhibited and (ii) the time interval within which the problem behavior occurred. Behavioral categories include aggression, property destruction, self-injurious behavior, and noncompliant behavior. No information is available on the reliability and validity of these instruments.

7.18.6 INTERVENTIONS

7.18.6.1 Pharmacological Interventions

A search of the medical, nursing, and psychological literature on treatment studies for aggression and agitation reveals that the vast majority of treatment studies on agitation and aggression are pharmacological. Several types of medication have been used in the treatment of agitated behaviors and aggression in older adults. These include neuroleptics, anticonvulsants, antidepressants, and antianxiety agents. A detailed consideration of the pharmacology of these agents is beyond the scope of this chapter. Studies of treatment efficacy are briefly reviewed.

7.18.6.1.1 Neuroleptics

Neuroleptics are the most commonly prescribed medications for reducing behavioral symptoms in older adults (Devenand & Levy, 1995). Their effects on agitation have been widely documented (e.g., Barnes, Veith, Okimoto, Raskind, & Gumbrecht, 1982; Coccaro et al., 1990; Schneider, 1990) although their mechanism of action has not been clearly established. In a meta-analytic review of 17 placebo-controlled studies of the use of neuroleptics with dementia patients, Schneider, Pollock, & Lyness (1990) reported that 18% of patients improved with neuroleptic treatment.

The use of neuroleptics for the management of aggression and agitation remains controversial because of the severity of associated side effects, including sedation, orthostatic hypotension, and akathesia (Finkel, 1993). Age-associated changes in metabolism increase the risk and severity of the side effects of neuroleptic use in older adults. Extrapyramidal reactions and tardive dyskinesia are also risk factors. Anticholinergic effects may exacerbate symptoms of dementia resulting in increased confusion, memory loss, and disorientation.

7.18.6.1.2 Benzodiazepines

Benzodiazepines are commonly used for the treatment of insomnia, anxiety, and agitation in older adults. In comparing the efficacy of benzodiazepines and neuroleptics in reducing agitation in cognitively impaired nursing home residents, Coccaro et al. (1990) reported a greater treatment response for neuroleptics. Side effects associated with benzodiazepines include sedation, cognitive impairment (Larson, Kukull, Buchner, & Reifler, 1987) and cerebellar ataxia resulting in an increased risk of falls (Ray, Griffin, Schaffner, Bough, & Milton, 1987). Paradoxically, when benzodiazepines are administered for agitation they may result in daytime sedation which, when coupled with the cognitive impairment associated with dementia, can result in increased irritability and agitation (Finkel, 1993). Further, withdrawal from benzodiazapines can result in serious disturbance, including insomnia, agitation, and psychosis (Wolf et al.,1989).

7.18.6.1.3 Beta blockers

Several studies describe the use of beta blockers for the treatment of agitation in elderly dementia patients (e.g., Greendyke, Kantor, & Schuster, 1986; Weiler & Goodman, 1987; Weiler, Mungas, & Burnick, 1988). Beta blockers such as propranolol affect agitation levels by blocking beta-adrenergic receptors and thereby decreasing sympathetic activity. Up to 1997, no well-controlled studies have evaluated the effects of beta blockers on agitation in cognitively impaired older adults. In a review of research on beta blockers for the treatment of agitation, Schneider and Sobin (1991) describe preliminary support for efficacy based on small samples of patients with various dementia diagnoses. Side effects involve both cardiovascular and central nervous systems. Propanolol is contraindicated in patients with sinus bradycardia, congestive heart failure, heart block greater than first degree, and bronchial asthma.

7.18.6.1.4 Other antianxiety agents

Anxiolytics such as buspirone are receiving increasing attention in the management of agitation and aggression in cognitively impaired older adults. Buspirone has fewer side effects than other antianxiety agents and the advantages of not producing memory impairment, psychomotor deficits, sedative, or addictive effects (Gelenberg, 1994). When side effects do occur they tend to be associated with higher initial doses (e.g. 10 mg t.i.d. rather than 5 mg t.i.d.). These include dizziness, nausea, and headache. Well-controlled treatment outcome studies of the effects of buspirone with dementia patients have not been conducted to date. However, the few studies that have been reported indicate that buspirone is effective in reducing aggression in dementia patients, with few side effects (Colenda, 1988; Herrmann & Eryavec, 1993; Jeanblanc & Davis, 1995).

7.18.6.1.5 Antidepressants

Several antidepressants have been used in efforts to reduce agitation in older adults. Serotonin uptake inhibitors have been receiving increased attention in the treatment of behavioral disturbance in dementia patients. Nyth and Gottfries (1990) evaluated the efficacy of citalopram for the treatment of emotional disturbance in 98 AD patients within a placebo-controlled group design. Significant improvement in agitation was reported for patients in the citalopram group.

7.18.6.1.6 Anticonvulsants

Evidence for the effectiveness of anticonvulsants for the treatment of agitation is limited to clinical case studies. A review of reports by Schneider and Sobin (1991) found 22 cases of agitated AD patients treated with anticonvulsants. Four patients were described as improved, with the remaining 18 not responding or developing toxicity. No well-controlled studies have evaluated the efficacy of these medications for the treatment of agitation in dementia patients. The most severe reactions associated with the use of carbamazine include dizziness, drowsiness, unsteadiness, nausea, and vomiting (Physician's desk reference, 1996).

7.18.6.2 Psychological Interventions

Empirical accounts of psychological interventions for managing behavior disturbances in older adults provide compelling support for preventative or proactive behavioral interventions (Lundervold & Lewin, 1992). Preventative approaches emphasize environmental design and the stimulus control of agitated behaviors and aggression. Given the paucity of information regarding the influence of the dementing disorders on response to consequences, interventions that attempt to *prevent* the occurrence of these behaviors may be the most judicious. Stimulus control interventions are described first.

7.18.6.2.1 Environmental stimuli

There are four components of the setting and sequence of events that warrant attention in determining whether agitated behavior or aggression are associated with environmental stimuli. The four components are: setting events, antecedent stimuli, patient response characteristics, and the consequences of the agitation or aggressive response.

(i) Setting events

When physiological or environmental setting events are identified as being reliably associated with aggressive responding, the context of the problem behavior can be modified to reduce the probability of the behaviors occurring. To illustrate, if aggression tends to occur during caregiving in the evening and not early in the day, then a reasonable intervention may be to reduce demands over the course of the day. Completing tasks early in the day will reduce the influence of fatigue and minimize the risk of a catastrophic reaction. If assessment reveals an association between specific environmental conditions and aggression (e.g., aggression occurs only when certain caregivers are providing care) the level of intervention will involve restructuring the physical or social context (e.g., altering the communication style of the caregiver).

In considering the role of antecedent stimuli associated with aggression and agitation the behavior of the caregiver clearly warrants attention. Specifically, the manner in which demands/requests are presented, even when quite benign in appearance, may provoke agitation or aggression. When verbal information or physical prompts are considered within the context of a patient's limited competencies it is clear that they should be presented individually and at a slower pace than normal. Instructions or requests should be made within the context of short sentences to accommodate impairment in language abilities and short-term memory. Caregiver eye contact and touch may also influence the likelihood of an undesirable response.

(ii) Response characteristics

A patient's emotional response before and during aggressive episodes may have implications for treatment planning. In a study of behavioral disturbance in dementia patients by Swearer et al. (1988), 63% of caregivers surveyed reported that the patient for whom they provided care exhibited one or more symptoms of anxiety, including general fearfulness, a fear of specific objects or events, restlessness, pacing, and appearing to worry over insignificant matters. Behavioral symptoms of anxiety were also found to be significantly associated with angry outbursts. Based on the observed association between aggression and anxiety, two treatment approaches warrant consideration. These involve the reduction of the anxiety-provoking characteristics of demand tasks and/or altering the consequences of the aggression.

The reduction of anxiety in cognitively impaired older adults can involve two strategies: (i) modifying the setting events or antecedent stimuli associated with the behavioral disturbance as described above, or (ii) implementing a distraction-based intervention to draw the patient's attention away from the distressing stimulus (e.g., instructing the caregiver to sing during caregiving episodes). Distraction-based techniques have been described for the reduction of anxiety in noncognitively impaired individuals (e.g., Beck, 1995; Barlow, 1988). The utility of such methods for dementia patients warrants further consideration by researchers.

If aggressive behavior tends to occur when demands to perform a task are placed on dementia patients, the aggressive response may be negatively reinforced by termination of demands. Further, if anxiety precipitates the aggression and the aggressive behavior results in a reduction of anxiety through termination of the anxiety-provoking stimulus (e.g. caregiver) the aggressive behavior can be viewed as adaptive since it may be the only readily accessed response in the patient's repertoire (Fisher & Swingen, 1996).

(iii) Social consequences

Assessment may reveal that the aggressive behavior of a dementia patient is contingently associated with social consequences (e.g., attention by caregivers). Differential reinforcement of incompatible behavior (DRI) may be a reasonable option to consider in this situation. To illustrate, Roseberger and MacLean (1983) described the implementation of this procedure in the treatment of a 79 year-old stroke patient residing in a nursing home. The patient was aphasic and partially paralyzed. Problem behaviors included physically aggressive behavior directed at staff, other residents, and visitors, throwing objects, smearing feces, and disrobing in front of visitors. Mechanical restraint and medication (e.g. Haldol and Mellaril) resulted in unacceptable side effects. Following assessment of the behaviors identified as the most disruptive, a DRI intervention was implemented wherein staff were instructed to greet the resident and praise her cooperation whenever she was observed to be behaving appropriately. In addition, problem behaviors resulted in a brief time-out from social attention. The intervention proved effective in that the resident's aggressiveness was reduced from 16 episodes per week to zero by the third week. Treatment effects were maintained at a 5 month follow-up.

A case study involving a 72 year-old man diagnosed with AD also demonstrates the effective contingent application of social consequences for reducing agitated behavior (Bakke et al., 1994). The patient had been prescribed buspirone for the agitation and had been expelled from two day treatment centers previously because of the agitation. On the basis of interview and observational data it was hypothesized that this man's frequent efforts to leave a work program and statements about going home were maintained by consistent attention from staff, while on-task, in-seat behavior resulted in social attention only 15% of the time. The intervention involved increasing the rate of tangible and social reinforcement contingent on working while incorporating efforts to reduce fatigue, discomfort, and boredom through restructuring of the work setting and schedule. Results indicated that this multicomponent program produced a significant decrease in agitated behavior while maintaining work productivity.

Understanding the contingencies of reinforcement associated with the behavior of dementia patients presents unique challenges for researchers and caregivers in that the progression in neuropathology limits the adequacy of traditional standards of treatment generalization and maintenance (Fisher & Carstensen, 1990). As is the case for physiologically based interventions, the effects of environmentally based interventions for dementia patients require continuous monitoring of changes in the reciprocal influence between behavior and the environment associated with deterioration in brain function. Stimulus control procedures, designed to prevent the occurrence of problem behaviors may be the most reasonable approaches to pursue until information regarding the efficacy of other environmentally based interventions is available (Fisher & Carstensen, 1990; Hussian, 1988).

7.19.1 INTRODUCTION

Urinary incontinence (UI) affects approximately 13 million Americans (National Kidney and Urologic Diseases Board, 1994). It is a common problem among 10–35% of all adults, affecting 30% of persons over age 60 years and more than 50% of nursing home residents (Diokno, Brock, Herzog, & Bromberg, 1990). Despite its high prevalence, urinary incontinence in the community often goes undiagnosed and underreported due to the stigma it holds (United States Agency for Health Care Policy and Research [USAHCPR], 1996). Outside and in the nursing home, incontinence is most often treated by physicians and nurses as a result of federal clinical practice guidelines that focus on medical assessment and treatment. Psychologists and behavioral therapists have played a role in treatment involving biofeedback strategies for use with cognitively intact persons suffering from incontinence. The purpose of the present chapter is to present how and why psychologists should play a broader role in the treatment and management of incontinence, particularly among cognitively and physically impaired frail people. Due to a number of associated conditions, this is particularly true for the large population of people who suffer from incontinence in nursing homes.

The primary role of physicians and nurses in incontinence care is dictated by the fact that best-practice guidelines specify that basic medical assessment of this condition is the first step to good clinical practice (USAHCPR, 1996). In the case of the community dwelling elderly, surgery and pharmacological treatment are often suggested by these assessments, and despite their invasiveness, are acceptable to relatively healthy people who suffer from incontinence. As noted above, historically, psychologists and other behavioral professionals have been responsible for developing and implementing incontinence interventions based on biofeedback strategies with people who are cognitively intact and capable of following the protocols that underlie biofeedback training. This work has been an important contribution to the management of incontinence in community dwelling populations. The present chapter will describe these traditional approaches to incontinence care.

The case will be presented in this chapter that, in addition to traditional roles, psychologists could and should play a broader role in the treatment and management of UI among cognitively and physically impaired persons. This point holds particularly true for the large population of people who suffer from UI in nursing homes, since behavioral deficits, depression, motivation, and a variety of other nonphysiological factors play a much larger role in the UI problems of these institutionalized elderly than for those who live in the community. Psychologists are specially trained to assess and manage these problems. Frail institutionalized elderly are not good candidates for many of the available invasive treatments, even if medical justification for these interventions are present. The most effective treatment of UI problems in the frail elderly has involved noninvasive behavioral interventions that have been directed towards both the patient and the caregiver. The skills of the behavioral scientist both for assessing the need for these interventions and for successfully implementing them is critical.

The present chapter first describes the prevalence and sequela of UI problems in both community dwelling and institutionalized populations. A simple classification scheme to describe the different kinds of incontinence symptoms is presented, along with a brief description of three major classes of treatment: pharmacological, surgical, and behavioral. Evidence describing the efficacy of these treatments is provided, with particular emphasis on the behavioral interventions. The final section of the chapter is devoted to the assessment and management of UI among institutionalized elderly. The potential role behavioral healthcare professionals could play in this assessment and treatment is also highlighted.

7.19.2 PREVALENCE, MORBIDITY, AND CONSEQUENCES

Urinary incontinence is most prevalent among the elderly in both community and institutional settings (National Kidney and Urologic Diseases Advisory Board, 1994). It affects 30% of persons over age 60 years who live in the community, about 35% of older patients in acute care hospitals, and over 50% of those living in institutions (Help for Incontinent People, 1994). Urinary incontinence has significant adverse physical, psychological, and financial effects. It is a leading cause of infection among frail older persons, is considered an embarrassing stigma by many of its sufferers, and has an estimated annual cost of over US$15 billion (National Kidney and Urologic Disease Advisory Board, 1994). Coupled with its role as a primary predictor of institutionalization, these negative outcomes clearly justify more aggressive efforts to identify, evaluate, and treat UI. These efforts are further justified by growing evidence that appropriate management can reduce the morbidity and cost of incontinence, particularly in institutionalized populations (Ouslander, Palmer, Rovner, & German, 1993).

Reported prevalence rates of UI vary considerably, depending on the population studied, how UI is defined, and how the prevalence information is obtained (Diokno et al., 1990). Among the population aged between 15 and 64 years the prevalence of UI in men is in the range 1.5–5% and in women is 10–30% (Burgio, Matthews, & Engel, 1991; Harrison & Memel, 1994).

Prevalence of UI ranges from 15% to 35% for noninstitutionalized adults above the age of 60 years, with women having twice the prevalence of men. Of these incontinent older adults, 25–30% have frequent (i.e., daily or weekly) incontinence episodes (Burgio et al., 1991;

Diokno, Brock, Brown, & Herzog, 1986). Approximately 53% of homebound elderly are incontinent (Noelker, 1987); this being similar to the prevalence rates reported for institutionalized elderly.

UI among nursing home residents is more severe and more commonly associated with fecal incontinence than in the community populations. Incontinent nursing home residents generally have multiple incontinence episodes throughout the day and night, and approximately 50% are also incontinent of stool (Ouslander & Fowler, 1985; Ouslander, Kane, & Abrass, 1982). The reported prevalence of UI in institutionalized populations ranges from 40% to 70%, and even higher, varying considerably between individual facilities depending on the case mix of functional impairment found within the resident population (Ouslander & Schnelle, 1995).

UI is associated with substantial morbidity and costs in the nursing home. It can predispose residents to skin irritation, exacerbating pressure ulcers and making them difficult to heal (USAHCPR, 1996); and can result in symptomatic urinary tract infections (Ouslander, Greengold, & Chen, 1987; Warren et al., 1987). It is also associated with falls among residents with nocturia and impaired balance or gait (Stewart, Moore, May, Marks, & Hale, 1992). The adverse psychological effects of UI among nursing home residents have been difficult to document due to issues of cognitive status and lack of willingness to report. However, incontinent residents who do not have severe dementia have reported being often embarrassed and frustrated by their condition (Ouslander, Morishita, et al., 1987).

Nursing home staff generally consider UI to be one of the most onerous and difficult conditions for which they provide care, and they perceive that a disproportionate amount of time is spent on the care of incontinent residents. The economic costs of UI in the nursing home have been estimated to be close to US$5 billion annually, including the cost of staff time, laundry, and supplies (Hu, 1994).

Thus, UI is a severe problem for large numbers of older people. Yet, this condition becomes even more devastating when it is considered that UI is often associated with a variety of more severe conditions. Among community dwelling older adults, UI is listed as a common geriatric syndrome associated with (i) a general decline in upper and lower body strength, (ii) sensory and emotional decline, and (iii) a high risk of institutionalization (Tinetti, Inouye, Gill, & Doucette, 1995).

Among nursing home residents, UI is associated with a high rate of hospitalization (Murtaugh & Freiman, 1995). Incontinent nursing home residents are susceptible to a high rate of infection requiring costly medical treatment both in the hospital and within the nursing home. Furthermore, the act of hospitalizing a nursing home resident is expensive from both quality of life and economic viewpoints. When older persons are hospitalized, they are at risk for experiencing a deluge of dependencies (Creditor, 1993).

Elderly nursing home residents often deteriorate in their functional status during hospital stays and develop problems unrelated to the cause of the admission (e.g., pressure sores). It seems clear that reducing hospitalization rates in nursing home residents will both improve the quality of life of residents and reduce the overall costs of healthcare. In view of these data, it has been argued that prevention programs targeting incontinent nursing home residents should be developed (Murtaugh & Freiman, 1995). The intent would be to reduce serious side effects connected with UI (e.g., urinary tract infections, skin infections), or prevent the condition from occurring. One example of such a prevention program is described in Section 7.19.6.6

To launch preventative programs and productive interventions effectively, it is essential first to distinguish among specific types of UI and to design efforts that are appropriately based on etiology and symptoms.

7.19.3 TYPES OF URINARY INCONTINENCE

7.19.3.1 Urge Incontinence

Urge incontinence is characterized by the involuntary loss of urine associated with a strong (or urgent) desire to void. Normally, as the bladder (detrusor) fills with urine, stretch receptors send signals to the spinal cord indicating the need for contraction. Under normal circumstances these contractions are inhibited through the central nervous system control. The person with urge incontinence has a reduced ability either to sense the urgency to empty the bladder or to inhibit contractions from the point that such signals are recognized.

This condition is usually associated with involuntary detrusor contractions referred to as detrusor instability (DI). This response is urodynamically confirmed by filling a person's bladder slowly with fluid via a catheter and measuring bladder contractions. In the case of urge incontinence, bladder contractions occur before the patient can report that they are unable to hold further fluid. DI is at times associated with neurologic disorders, but can also occur in individuals who appear to be neurologically intact.

In cases where neurological lesions are established, the DI is distinguished as detrusor hyperreflexia (DH). The most common neurological disorder associated with DH is stroke. A second neurodynamic diagnosis associated with the symptom of urge incontinence in frail elderly people is detrusor hyperactivity with impaired bladder contractility (DHIC) (Resnick & Yalla, 1985). DHIC results in involuntary bladder contractions. However, symptomatically, patients must strain actually to empty their bladders. Patients with DHIC generally have symptoms of urge incontinence and elevated postvoiding residual volumes (i.e., the amount of urine left in the bladder after a person voluntarily attempts to empty his or her bladder). Clinically, the amount left in the bladder can be determined either by ultrasound or by catheterizing the person after they void and draining what remains in the bladder.

7.19.3.2 Stress Incontinence

Stress incontinence is characterized by the involuntary loss of urine during physical movements that increase intra-abdominal pressure, such as coughing, sneezing, laughing, or other physical activities. Stress incontinence is established if the urine loss is coincident with an increase in intra-abdominal pressure, but occurs in the absence of a detrusor contraction or an overdistended bladder (USAHCPR, 1996). The most common cause of stress incontinence occurs in women as intra-abdominal pressure results in a significant displacement of the urethra and bladder during exertion.

Stress incontinence may also be caused by a deficiency in the sphincter muscle that closes off the bladder outlet. Normally, the sphincter is relaxed when voluntary bladder emptying begins, but closes off the bladder outlet during other times. In women, this incontinence is commonly a result of multiple surgical procedures, low estrogen levels due to age or other causes, or both. In these cases, the urethra sphincter is unable to generate enough resistance to retain urine in the bladder when bladder pressure is raised. Patients with stress incontinence can leak continuously or with minimal exertion.

It is not unusual for people to have a combination of urge and stress incontinence. When both symptoms are present, the incontinence is called mixed. Mixed incontinence is particularly common in older women.

7.19.3.3 Overflow Incontinence

Overflow incontinence is the involuntary loss of urine associated with overdistension of the bladder due to a high volume of urine. Overflow incontinence may manifest itself in a variety of symptoms similar to those of stress incontinence. It may be caused by an underactive bladder (unable to contract efficiently) or a bladder-outlet obstruction leading to overdistension and overflow. The bladder may be underactive due to drugs, neurologic conditions, spinal cord injury, or as a side effect of diabetes. In men, overflow incontinence is often associated with obstruction caused by the prostate; outlet obstructions are rare in women. Overflow incontinence is best diagnosed by measuring a patient's postvoid residual volume, as described in Section 7.19.3.1.

7.19.3.4 Functional Incontinence

Functional incontinence is characterized by involuntary urine loss due to factors outside the lower urinary tract. For example, if a patient has no stress or urge symptoms or a high postvoid residual, but is incontinent because he or she cannot reach the bathroom in a timely manner, it may be termed functional incontinence. Functional incontinence is typically diagnosed in people with physical or cognitive impairment. Caution is recommended in making this diagnosis, in that it should only be made after other causes have been excluded. Because mobility and cognitive impairment may occur in patients suffering from other types of UI, it is essential first to rule out those types that could respond to specific therapies.

The most typical treatment for functional incontinence involves improving the patient's functional status, modifying transient causes for the incontinence (e.g., fecal impaction), and reducing environmental barriers to toileting or providing sufficient toileting assistance to avoid incontinence episodes. These latter treatments are suggested for consideration even if a lower urinary tract abnormality is present, since incontinence may be exaggerated by immobility and cognitive factors. The assessment and treatment of incontinence is now discussed.

7.19.4 BASIC ASSESSMENT

Best-practice guidelines recommend that all incontinent residents should undergo a basic evaluation that includes a history, physical

Table 1 Potentially reversible conditions that may contribute to urinary incontinence in nursing home residents, and the management of these conditions.

Conditions	*Management*
Impaired ability or willingness to reach a toilet	
Delirium	Diagnosis and treatment of underlying cause(s)
Illness, injury or restraint interfering with mobility	Regular toileting assistance. Use of toilet substitutes Environmental alterations.
Depression	Appropriate pharmacological and/or nonpharmacological treatment
Irritation or inflammation in or around the lower urinary tract	
Urinary tract infection (symptomatic with frequency, urgency, sudden onset, or worsening of UI, unexplained fever or functional decline)	
Antimicrobial therapy[a]	
Atrophic vaginitis/urethritis	Oral or topical estrogen[b]
Stool impaction	Disimpaction Use of stool softeners and laxatives as appropriate Adequate mobility and fluid intake.
Increased urine production	
Metabolic (hyperglycemia, hypercalcemia	Improved control of diabetes Therapy for hypercalcemia if indicated by underlying cause
Excess fluid intake	Reduction in diuretic fluid intake (e.g., caffeinated beverages)
Volume overload	
Venous insufficiency with edema	Support stockings Leg elevation Sodium restriction Diuretic therapy
Congestive heart failure	Medical treatment
Drug side-effects	
Rapid-acting diuretics causing frequency and urgency	Discontinuation of offending medication as possible Dosage reduction or modification of scheduling
Rapid-acting diuretics causing frequency and urgency	
Anticholinergics, narcotics, calcium channel blockers, α adrenergic agonists (in men) causing urinary retention	
α Adrenergic antagonists causing urethral relaxation and stress incontinence	
Psychotropic drugs with sedative or extrapyramidal effects causing sedation and immobility that interfere with toileting	

[a] For nursing home residents with bacteriuria (with or without pyuria) who have chronic, stable symptoms of UI and no other symptoms of urinary tract infection, antimicrobial therapy is not indicated (see text). [b] See text for specific recommendations.

examination, measurement of postvoiding residual volume, and urine analysis. This basic evaluation has three objectives:

(i) to identify potentially reversible factors for incontinence (e.g., stool impaction, drug side effects, and other factors, as listed in Table 1);

(ii) to identify serious underlying conditions that may require further urologic, gynecologic, or urodynamic evaluation (see Table 2 for listed conditions); and

(iii) to determine the types of incontinence and the appropriate plan for their management.

Depending on the outcomes of this basic evaluation, three general classes of treatment and several combinations of treatments may be justified. The three primary classes of treatment are now discussed.

Table 2 Conditions that may require further urologic, gynecologic, or urodynamic evaluation.

Conditions	*Comments*
History	
Incontinence with recurrent symptomatic urinary tract infections	Must first exclude structural abnormality or pathologic condition in the urinary tract predisposing the patient to symptomatic infection
Physical examination	
Marked pelvic prolapse protruding through vaginal introitus	Consider surgical repair or pessary management to prevent discomfort and tissue erosion
Possible prostate cancer	Surgical intervention to cure cancer would not be appropriate for most nursing home residents; however, cancer diagnosis may be important in managing the incontinence and other complications
Urinalysis	
Hematuria (sterile)	Consider urologic evaluation to identify pathologic conditions of the urinary tract
Determination of postvoid residual volume	
Residual volumes > 200 ml	No precise cutoff point can be recommended; however, residual volumes > 200 ml are abnormal and should prompt consideration of further evaluation of the urinary tract to identify complications (e.g., hydronephrosis or renal function impairment) and determine the cause of the retention (e.g., obstruction, impaired bladder contractility)

7.19.5 TREATMENT OPTIONS

7.19.5.1 Pharmacological Interventions

The most common pharmacological interventions involve medications given for detrusor instability with urge symptoms and for stress incontinence. Evidence for the efficacy of these medications is most complete for anticholinergic drugs, which are designed to limit the contractility of the normal bladder and which probably also reduce instable contractions in the bladder.

7.19.5.1.1 Drug interventions for urge incontinence

The pharmacological agent which has been most often tested in trials to reduce urge incontinence symptoms is oxybutynin. Oxybutynin proved superior to placebos in six studies of middle-aged patients, reducing UI frequency by 15–58% more than did the placebo (Holmes, Montz, & Stanton, 1989; Moore, Hay, Imrie, Watson, & Goldstein, 1990; Riva & Casolati, 1984; Tapp, Cardozo, Versi, & Cooper, 1990; Thuroff et al., 1991; Zeegers, Kiesswetter, Kramer, & Jonas, 1987). In two of these studies, 43–67% of the subjects became subjectively continent with oxybutynin, a significantly larger proportion than found in those receiving placebo.

To test its efficacy with a nursing home population, in a randomized clinical trial of nursing home residents, oxybutynin was administered only to those residents who failed to respond to a noninvasive behavioral intervention (prompted voiding) (Ouslander et al., 1995a). Oxybutynin was given as a supplement to prompted voiding for those residents who failed to reduce their UI level with the prompted voiding intervention to less than one episode per day. Oxybutynin showed very modest effects in this target group of residents, and did not reduce UI to levels which were regarded as clinically significant. Thus, given the cost of the medication and its potential negative side effects (dry mouth, constipation, urine retention), it is not recommended for the general treatment of UI among nursing home residents.

An expert consensus panel convened by the USAHCPR summarized the research findings for the use of pharmacological agents to treat detrusor instability as follows:

> Pharmacotherapy, at least in short-term trials, appears to benefit some patients with UI due to detrusor instability. However, involuntary bladder contractions are usually not abolished, the warning time between the appreciation of the need to

> void and the onset of bladder contraction is usually not affected, the degree of improvement is modest and cure is uncommon. In addition, many of these medications are costly and most have bladder side effects. These drugs should be used only in conjunction with a voiding schedule or behavioral intervention and only if other factors contributing to UI have been addressed. (USAHCPR 1996, p. 47)

7.19.5.1.2 Drug interventions for stress incontinence

Medications have also been used for stress incontinence, the purpose being to enhance muscle control in the bladder neck, bladder base, and proximal urethra. It is anticipated in these cases that the drug will stimulate muscle contraction in these areas and increase bladder outlet resistance. Increasing resistance should result in less urine loss when intra-abdominal pressure is raised. The data from controlled trials of medications that stimulate such muscle contraction are less clear than for drugs given for detrusor instability. The expert USAHCPR panel concluded that pharmacological therapy treatment for stress incontinence appears to result in few cures, but may cause subjective improvement in 20–60% of patients over placebo responses.

Estrogen replacement therapy is also considered a potential treatment for stress incontinence. Presumably estrogen replacement therapy will increase the vascularity, tone, and responsiveness of the urethra muscle. This, in turn, should increase bladder resistance and decrease stress incontinence. The exact mechanism of how estrogen may work, however, is unknown.

Fantl, Cardozo, & McClish, (1994), for The Hormones and Urogenital Therapy Committee, provided a meta-analysis of estrogen effects from six randomized controlled trials and 17 uncontrolled clinical series. Positive results were found for all subjects in the trials, representing a significant number of patients who presented with stress incontinence symptoms.

7.19.5.2 Surgery

Surgical intervention for UI is a consideration for a small but important subgroup of nursing home residents and a much larger group of community dwelling elderly. Since UI is not a life-threatening problem, elective surgery should be considered only if the patient reports strong quality-of-life concerns. It is also recommended that in most, if not all, cases surgery be considered only after less invasive pharmacological or behavioral treatments have proven ineffective.

Two major types of surgery are used to treat UI. First, women with stress incontinence associated with significant pelvic prolapse and urethral hypermobility may benefit from bladder-neck suspension and repair of the pelvic prolapse. Although studies have not been done in the nursing home population, the short-term (1–5 years) success of this type of surgery for properly selected older women is approximately 75%, success being defined as a significant reduction or elimination of wetness USAHCPR, 1996). Surgical placement of artificial urinary sphincters has been used for younger patients with stress incontinence associated with intrinsic urethral deficiency. This requires a relatively major surgical procedure and is probably not appropriate for nursing home residents or very frail older people. Periurethral injections of collagen have recently been approved for patients with intrinsic urethral deficiency. It is unknown what the mechanism of the effects are, but periurethral injection has reportedly been effective in younger patients.

The other type of surgical intervention for UI is the removal of anatomical obstruction, most commonly an enlarged prostate in men or a urethral stricture. Newer, less invasive techniques are now available for the surgical relief of obstruction in men and may be especially appropriate for consideration in frail, older nursing home residents. Detailed discussion of the evaluation and surgical treatment of lower urinary tract obstruction is beyond the scope of the present chapter. However, it is important to note that candidates for surgery who are suspected of having obstruction should be referred for complex urodynamic evaluation.

7.19.5.3 Behavioral Interventions

Behavior-based treatment strategies are a relatively noninvasive form of treatment for UI and can be effective in many cases. Behavioral therapies can be divided into (i) caregiver-dependent techniques for patients with cognitive and motor deficits, and (ii) those requiring active rehabilitation and education of the patient. These distinctions are arbitrary and require a careful analysis of how the patient's abilities match the performance requirements of a specific behavioral protocol. For example, most biofeedback interventions require that a patient follow multistep instructions, which may be beyond the ability of a cognitively impaired frail older adult. Therefore, in order to characterize the full array of available behavioral techniques for the large range of cognitive and functional abilities represented among incontinent people, this section of the present chapter describes techniques ranging from those that require the most active involvement on the part of the patient to those that require the least.

7.19.5.3.1 Bladder retraining

Bladder retraining is strongly recommended for the management of urge and mixed incontinence. The goal of this training is to build bladder capacity or to increase intervals between voiding. This, in turn, will reduce the probability of involuntary contractions. Bladder training has been used primarily to manage incontinence caused by DI. This form of training has few side effects, but is difficult to implement in cognitively impaired persons.

Bladder retraining (also termed "bladder training") has many variations, but generally consists of three primary components: (i) education, (ii) scheduled voiding with systematic delay of voiding, and (iii) positive reinforcement.

The education component usually involves a combination of written, visual, and verbal instructions that describe the physiology and pathophysiology of the lower urinary tract. This provides the background understanding considered useful in promoting adherence to the behavioral protocol.

Scheduled voiding and delay of voiding involves retraining the patient in resisting or inhibiting the sensation of urgency, to postpone voiding, and to urinate according to a timetable rather than according to urge (McCormick & Burgio, 1984). Behavioral approaches are often designed to distend the bladder by adjusting fluid loads and/or delaying voiding. The goal is to progressively increase the volumes retained in the bladder as well as the intervals between voids (Keating, Schulte, & Miller, 1988). If the patient is unable to meet the delay goal, the schedule is adjusted and the interval reset. Generally, the interval goal is initially set between two and three hours, with consideration given to the patient's baseline. This technique is not usually applied during sleeping hours. Once established, the goal interval is progressively increased and new goals accomplished through the use of distraction or relaxation techniques. The patient is thus "trained" to delay voiding when the urge to void occurs.

Several reports demonstrate that bladder training is effective in reducing UI (Fantl et al., 1991; Ferrie, Smith, Logan, Lyle, & Paterson, 1984; Pengelly & Booth, 1980). Fantl et al. (1991) conducted a controlled, randomized study of 131 women with sphincteric incompetence and unstable detrusor function. Subjects participated in a bladder-training program that included patient education, behavioral strategies to decrease urge, and scheduled voiding. Of the 60 women in the treatment group, 12% became dry and 75% had at least a 50% reduction in the number of UI episodes. Control subjects did not have significant changes in incontinent episodes. The magnitude of the effect was somewhat larger in cases of DI and the effect of bladder training was maintained after six months.

7.19.5.3.2 Pelvic muscle rehabilitation

Pelvic muscle rehabilitation is designed to strengthen the voluntary muscles that contribute to the closing force of the urethra and to support the pelvic structures. Underlying these technologies is a strategy directed toward stress symptoms; but there is some evidence that it can also be successful with DI and urge incontinence as well. When pelvic muscle rehabilitation exercises are done alone they often are called Kegel exercises. However, these exercises are also frequently supplemented by biofeedback training designed to increase awareness of pelvic muscle functioning.

The first step in pelvic muscle exercises (PMEs) is to help the patient develop a better awareness of pelvic muscle function and control. PMEs are performed by voluntarily contracting the perivaginal muscles and anal sphincter as if to control urination or defecation (Rose, Baigis-Smith, Smith, & Newman, 1990). The goal is to accomplish this with minimal contraction of abdominal, buttock, or inner thigh muscles. Patients are trained to sustain a contraction for at least 10 seconds, followed by an equal period of relaxation. It is a goal to progressively increase the contraction time. PMEs should be performed about 30–80 times a day for at least eight weeks, and may need to be continued indefinitely. Patients should be taught to contract the pelvic muscles both before and during an incident when leakage may occur.

The most effective use of PME to date has been reported in an uncontrolled study by Benvenuti et al. (1987). Patients were provided with 10 hours of training, including 20 sessions for practice of PMEs and other behavioral strategies, and an intensive home program. Subjects were 20 women aged 35–65 years (mean age 50.8 years). This protocol resulted in a 95% reduction in incontinence episodes. PME also has proven effective in the treatment of older adults in a study by Flynn, Cell, and Luisi (1994) that involved treatment for transient UI in 37 older adults receiving home nursing care (mean age 76 years).

The intensity of the PME program significantly affects physiological and functional outcomes. Bo, Hagen, Kvarstein, Jorgensen, and Larsen (1990) found significantly greater reductions in UI among a group of patients receiving ongoing training of increasing intensity over a period of six months as compared to a group that received only a single session of instruction and a home exercise program. The group receiving the ongoing instruction reported a 60.1% cure/improvement rate compared with 17.3% among the home exercise group. This study also found significant differences between these groups in physiological measurements of improved pelvic strength. This finding indicates a possible systematic relationship between symptom reduction and objective physical changes. Benvenuti et al. (1987), Elia and Bergman (1993), and Mouritsen, Frimodt, and Moller (1991) also report findings that PME has the potential to change muscle physiology.

In all cases of PME training, patients must show the capability of memorizing multistep instructions and be motivated to practice exercises when not with the therapist. These performance requirements limit the use of pelvic floor muscle rehabilitation for cognitively impaired individuals.

(i) Pelvic muscle rehabilitation: biofeedback

Biofeedback therapy generally uses electronic or mechanical instruments to sensitize patients to their physiological activity. This sensitization is generally accomplished through the use of auditory, visual, or other feedback. The goal is to train patients to identify and modify physiologic responses that mediate bladder control. Studies reporting various applications of biofeedback combined with behavioral treatment report a range of 54–87% improvement in UI across various patient groups (USAHCPR, 1996).

Biofeedback protocols differ in their use of reinforcement or feedback, as well as in the measurement system used to establish this feedback. The biofeedback protocol that has achieved the largest and most consistent reduction in UI episodes (75.9–82%) simultaneously reinforces pelvic muscle contraction, inhibition of abdominal contraction, and inhibition of detrusor contraction (Burgio, Robinson, & Engel, 1986; Burgio, Stutzman, & Engel, 1989; Burgio, Whitehead, & Engel, 1985; Burton, Pearce, Burgio, Engel, & Whitehead, 1988; McDowell, Burgio, Dombrowski, Locher, & Rodriguez, 1992). The presumed benefit of this approach, defined by a multimeasurement procedure, is that it reinforces pelvic floor contraction with moment-to-moment feedback, thus providing the patient with highly specific internal references to upgrade muscle contraction. Combining bladder and sphincter biofeedback also allows teaching pelvic muscle contraction in response to increasing bladder volume and observed detrusor activity.
